About the Editor

Neil J. Salkind received his Ph.D. from the University of Maryland in Human Development and has been a faculty member at the University of Kansas for 34 years. He has given more than 125 presentations and is the author of several college-level textbooks, including *Statistics for People Who Think They Hate Statistics* (Sage), *Exploring Research and Theories of Human Development* (Sage), and *Exploring Research* (Prentice Hall). He was editor of *Child Development Abstracts and Bibliography* for 13 years and lives in Lawrence, Kansas.

Introduction

Educational psychology is a special field of endeavor because it strives to apply what is known about many different disciplines to the broad process of education. In the most general terms, you can expect to find topics in this area that fall into the categories of human learning and development (across the life span), motivation, measurement and statistics, and curriculum and teaching. More specifically, the educational psychologist studies such topics as aggression, the relationship between poverty and achievement in schools, lifelong learning, quantitative methods, and emerging adulthood. Educational psychology is truly a diverse and fascinating field of study and unlike other social and behavioral sciences. Its significance for application to the real needs of both children and adults cannot be overestimated.

The importance of all these topics is not limited to the college classroom or academic lecture circuit. Rather, the ability to understand complex issues such as vouchers, early intervention, inclusion, cultural diversity, and the role of athletics in the schools (to mention only a few examples) carries important implications for public policy decisions. The encyclopedia you have in your hands includes some technical topics related to educational psychology, but for the most part, it focuses on those topics that evoke the interest of the everyday reader.

Although there are hundreds of books about different topics in education and educational psychology and there are thousands of university and private researchers pursuing more information about these topics, most of the available information tends to be found in scholarly books and scholarly journal articles—usually out of the reach of the everyday person. In fact, there are few comprehensive overviews of the field of educational psychology, and the purpose of this multivolume *Encyclopedia of Educational Psychology* is to share this information in a way that is, above all, informative without being overly technical or intimidating.

Through more than 275 contributions, experts provide overviews and explanations of the major topics in the field of educational psychology.

How were these topics selected to be included in this encyclopedia? The underlying rationale for topic selection and presentation comes from the need to share subjects that are rich, diverse, and deserving of closer inspection with an educated reader who may be uninformed about educational psychology. Within these pages, the contributors and I provide the overview and the detail that we feel is necessary to become well acquainted with topics that fairly represent the entire field.

Like many encyclopedias, the *Encyclopedia of Educational Psychology* is organized in alphabetical order, from A through Z. However, there are particular themes under which the information and the entries could be organized conceptually. These themes, or major topic areas, constitute the Reader's Guide, which appears on page xi. Categories such as Classroom Management; Ethnicity, Race, and Culture; Families; Intelligence and Intellectual Development; Learning and Memory; and Peers and Peer Influences are only a few that help organize the entire set of contributions.

The Process

Sage developmental editors Diana Axelsen and Carole Maurer, the encyclopedia's managing editor Kristin Rasmussen, and I started the process of compiling all the entries in the encyclopedia by asking experts in the general field, as well as the more specific areas (again, see the Reader's Guide), what topics they feel should be included to make a reference work that provides a general overview of the field. We tried to ensure that these entries included topics that would be of interest

to a general readership and not terms that were too highly technical or too far removed from the interests of the everyday reader. This list was reviewed and revised many times, until we felt that it was a comprehensive set of topics that best fit the vision for the encyclopedia.

It was no surprise that this list would be edited and revised as we worked and as authors were recruited to write particular entries. Enthusiastic authors would suggest adding topics that might have been overlooked as well as removing topics that might have no appeal. These suggestions were taken into consideration as the final list that forms the A through Z collection was assembled.

The next step was to assign a length to each entry, which ranges from 1,000 words for shorter articles (such as the one on Parent–Teacher Conferences) to more than 5,000 words for major entries (such as the one on Literacy). The scope of different entries varies depending on their importance to the field and the amount of information we thought important to include. In between, there are entries that are 2,000 and 3,000 words in length. Sometimes authors would request that the length be extended because they had so much information they wanted to include and they felt that the limitation on space was unwarranted. In most cases, it was not a problem to allow such an extension.

The final step was the identification of authors. This took place through a variety of mechanisms, including experts' recommendations, professional and personal experiences of both the managing editor and me, contact with authors of journal articles and books that focus on a particular area directly related to the entry, and requests for referrals from other individuals who are well known in the field. It is a testament to how deeply these authors are committed to their own work and to sharing it with others that they gave freely of their time and advice.

Once authors were identified and invited, and once they confirmed that they could participate, they were sent detailed instructions and given a deadline for the submission of their entry. The results, after editing, layout, and other production steps, are in your hands.

How to Use This Book

Like a good meal, a book is meant to be fully enjoyed, and whereas most people believe that encyclopedias are only used for reference purposes, we hope that this two-volume encyclopedia is an easy one to sit with and browse.

A primary goal of creating this set of volumes was to open up the broad discipline of educational psychology to a wide and general audience. That's why you will find topics that are of particular interest to the general public, such as vouchers, Head Start, divorce, learning communities, and charter schools.

Take these books, find a comfortable seat in the library, browse through the topics, and read the ones that catch your eye. We're confident that you'll continue reading about the field and will use the suggestions for such contained in the Further Readings list following each entry.

Should you want to find a topic within a particular area, consult the Reader's Guide, which organizes entries within this two-volume set into general categories. Using this tool, you can quickly move to an area or a specific topic that you find valuable and of interest.

Acknowledgments

My most appreciative thanks to Diane Axelsen and Carole Maurer. Their title is developmental editor, but they are the engineers, timetable keepers, track fixers, customs agents, and chefs who keep the train running and the people who are on it (the editorial staff and all the contributors) happy and productive. It is not an exaggeration to say that this encyclopedia would not have happened without their selflessness, diligence, patience (such as, "Okay Carole, I promise I'll get it to you by tomorrow"), and nurturance. I am in their debt.

My sincere thanks and appreciation go to the managing editor, Kristin Rasmussen, an advanced graduate student at the University of Kansas, who managed the submissions from the recruitment of authors to the transmission of the final documents to Sage. Kristin completed these tasks with enthusiasm, initiative, and perseverance in answering endless questions through thousands of e-mails to hundreds of authors. Thank you sincerely.

Neil J. Salkind

June, 2007

A

When I was a boy of fourteen, my father was so ignorant I could hardly stand to have the old man around. But when I got to be twenty-one, I was astonished at how much he had learned in seven years.

—Mark Twain, "Old Times on the Mississippi," *Atlantic Monthly*, 1874

ABSTINENCE EDUCATION

Abstinence education advocates abstinence as the 100% sure way to prevent pregnancy and the transmission of sexually transmitted diseases (STDs). The U.S. teen pregnancy rates have been decreasing since the 1990s, but of all of the developed countries in the world, the United States still has the highest teen pregnancy rates. The Centers for Disease Control and Prevention estimate that approximately 19 million new STDs occur each year, almost half of them among young people ages 15 to 24. Teens with STDs are impacted emotionally and physically, and the annual medical cost directly attributed to STDs in the United States is well over $13 billion. Communities are looking for answers on how to address the complex issues of teen pregnancy and STDs. Abstinence education is seen as one such answer.

The premise of abstinence education is that abstinence is the best choice for youth when it comes to making sexual decisions. Schools and communities can decide what type of programming to provide to their young people. The current federal initiatives are driving the abstinence-until-marriage initiatives, and anyone receiving federal funding must adhere to specific guidelines. The evaluation of these programs shows some short-term impacts on attitudes and behavioral intent, but long-term studies on behavior are mixed. This entry provides a general overview of sexuality education, abstinence education, federal funding for abstinence programming, guidelines for selecting programs, and evaluation of abstinence programs.

Sexuality and Abstinence Education

Parents are the primary educators of their children. Some parents may not feel comfortable broaching the topics with their children, may not have the factual knowledge to share with their children, or may not know how to talk to their children in a developmentally appropriate manner. Who else can teach the children? The vast majority of children attend public school, and schools are a logical place to provide sexuality education. Programming may be taught by teachers, health educators, nurses, doctors, or other credentialed professionals. No matter who is teaching the children, it is important for the school to verify the accuracy of the curriculum, evaluate the credentials of the provider, and be sure the curriculum meets with school district policies.

Sexuality education guidelines are typically established at the state level and carried out at the local level. Almost every state mandates sexuality education, and some mandate abstinence education. Districts and communities may choose from a range of

programs, from comprehensive sexuality education programs—which may cover birth control, a range of sexual behaviors, gender identity, life skills, and anatomy and physiology—to abstinence-only-until-marriage programs, which only discuss sexual activity within the context of marriage. School districts typically create policies delineating what type of sexuality education will be taught in what grades and what topics will be covered. Most school districts allow students, with parental permission, to opt out of sexuality education.

Sexuality education has changed from the broader ranging comprehensive sexuality education in the 1970s to the current, more narrowly focused, federally funded abstinence-only-until-marriage programs of the late 1990s and today. The change in program focus can be attributed to a concern among some parents and communities that comprehensive sexuality education was teaching students how to have sex or was sending the mixed message "Do not have sex—but if you do, be sure to use protection." Some of the disfavor arose from not clearly delineating what could and should be taught in the schools, that is, concerns over what was developmentally appropriate and what was the purview of the parent. Some people felt abstinence education was a means of establishing moral purity and strengthening marriage.

Abstinence education proponents support the one message of abstinence from sex and do not want students to receive the mixed message "Yes, remain abstinent—but if you are not abstinent, then remember to use birth control." Many abstinence education programs do not discuss birth control except to describe their failure rates. Components of abstinence education programs can vary, but generally the focus is on the harm that comes from sexual intercourse and early sexual involvement. Depending on the school district, curricula components vary and may or may not include anatomy and physiology, life skills, communication skills, or refusal skills components.

The curricula are created by a variety of people, including teachers, school districts, health educators, faith-based groups, private businesses, or community members.

Abstinence-plus proponents believe abstinence is the best choice for young people when it comes to making decisions about sex. The "plus" in abstinence-plus often includes life skills components such as goal setting, life planning, communication, anatomy and physiology, and information on contraception. The plus component refers to the ability of the teacher to answer student questions, provide information about contraceptives, or possibly refer the student for information on contraceptives.

The philosophy of the current abstinence-only-until-marriage, also known as abstinence-only, programs is that sexual intercourse and sexual activity should happen only between a man and woman and only when they are married. There is no discussion of contraception except to discuss failure rates, and no programs may advocate for the use of contraceptives. Each program adheres to a set of guidelines as established by law in 1996. The next section discusses federal funding of abstinence-only programs and the program guidelines.

Federal Funding

The first federal funding of abstinence programs was created in 1981 with the Adolescent Family Life Act as Title XX of the Public Health Service Act. According to the Office of Adolescent Pregnancy Programs, the Adolescent Family Life (AFL) program supports demonstration projects to develop, implement, and evaluate program interventions to promote abstinence from sexual activity among adolescents and to provide comprehensive health care, education, and social services to pregnant and parenting adolescents. The program supports two basic types of demonstration projects: (1) prevention demonstration projects to develop, test, and use curricula that provide education and activities designed to encourage adolescents to postpone sexual activity until marriage; and (2) care demonstration projects to develop interventions with pregnant and parenting teens, their infants, male partners, and family members in an effort to ameliorate the effects of too-early-childbearing for teen parents, their babies, and their families. The AFL program also funds grants to support research on the causes and consequences of adolescent premarital sexual relations, pregnancy, and parenting. The Title XX funds not only help the teens and families they serve directly, but they also provide valuable information and evaluation findings that can serve as a basis for future strategies. Every program that receives AFL grant funds is required to include an independent evaluation component. This ensures that the lessons learned by each community will benefit others in the future.

In 1996, federal abstinence education programs narrowed the definitions of abstinence when Section 510(b) of Title V of the Social Security Act,

P.L. 104–193 was signed into law by President Bill Clinton. The abstinence-only federal funding was created as part of "welfare reform," or the Temporary Assistance for Needy Families Act (TANF). This third funding stream provides grants to states for abstinence-only-until-marriage programs. The abstinence-only-until-marriage educational or motivational programs must adhere to the following eight criteria as established by law:

1. Has as its exclusive purpose teaching the social, psychological, and health gains to be realized by abstaining from sexual activity

2. Teaches abstinence from sexual activity outside marriage as the expected standard for all school-age children

3. Teaches that abstinence from sexual activity is the only certain way to avoid out-of-wedlock pregnancy, sexually transmitted diseases, and other associated health problems

4. Teaches that a mutually faithful monogamous relationship in the context of marriage is the expected standard of sexual activity

5. Teaches that sexual activity outside of the context of marriage is likely to have harmful psychological and physical effects

6. Teaches that bearing children out-of-wedlock is likely to have harmful consequences for the child, the child's parents, and society

7. Teaches young people how to reject sexual advances and how alcohol and drug use increases vulnerability to sexual advances

8. Teaches the importance of attaining self-sufficiency before engaging in sexual activity

As of 1997, all abstinence projects funded under the Office of Adolescent Pregnancy Prevention must adhere to the eight criteria. The funded projects must be evaluated, and the curricula must be medically accurate.

Title V grantees cannot provide educational programming that goes against any one of the criteria listed previously in this section, but the states have the latitude to focus on only a few of the criteria. The states can direct the funding to schools, community-based organizations, health districts, media campaigns, or faith-based entities. Each state has the discretion to decide who receives the funding, how programs are delivered, and if and how they will be evaluated.

In October 2000, the federal government expanded the abstinence-only projects and created Special Projects of Regional and National Significance–Community-Based Abstinence Education (SPRANS–CBAE). The SPRANS grants are awarded to states and community organizations and can fund only abstinence-only-until-marriage programs. In 2005 oversight of the SPRANS–CBAE grants was moved from the Maternal and Child Health Bureau to the Administration for Children and Families (ACF); both are within the U.S. Department of Health and Human Services (HHS). This program is now known as Community-Based Abstinence Education (CBAE). The program requirements have been tightened; to receive funding, each program now must adhere to all eight criteria. Process evaluation is now required for new grantees, but programs do not have to measure impact on program participants. So how does one select an abstinence program?

Selecting and Evaluating Programs

Abstinence education programs are evolving, and the types of programs offered are vast in terms of quality, cost, and effectiveness. When choosing a program, educators can look for teacher training, medical accuracy, evidence of effectiveness with similar populations, costs, whether the program is theoretically based, and how it fits with community guidelines. Other considerations include whether the program is taught by a teacher or peers and how much time can be devoted to the program. Programs can range from a single 1-hour presentation to 25 sessions over 5 weeks. The curricula and desired learning outcomes should coincide. A final component is the effectiveness of the program; currently, long-term research on the effectiveness of abstinence education is limited to a few programs, and the results are mixed. Few rigorous, long-term studies focusing on behavioral outcomes have been conducted on specific abstinence-only programs. The Office of Adolescent Pregnancy Programs (OAPP) does require all of its abstinence programs to be evaluated, and most of the published abstinence evaluations are former OAPP projects. Most of the programs have shown immediate differences in attitudes and intent to remain abstinent. One problem with the evaluations of many abstinence programs is the limited ability to assign students to experimental or control groups, the presence of follow-up evaluations, and the limited sample sizes.

Research is needed to determine the long-term impacts on behavior.

ACCELERATION

The classical understanding of the term *acceleration* is progress through an educational program at a rate faster, or at an age younger, than conventional. This is now referred to, more appropriately, as *academic acceleration* and is based on the premise that each child has a right to realize his or her potential.

Academic acceleration is valid pedagogy, is grounded in and supported by research, and is an appropriate response to the educational and social needs of a student whose cognitive ability and academic achievement are several years beyond those of their age-peers. Yet worldwide it is an educational option little used. Even though the research on acceleration is so uniformly and distinctly positive and the benefits of well-administered acceleration are so unequivocal, educators are reluctant to accelerate children, and some educational systems proscribe its transparent use.

This entry presents an outline of current theory of academic acceleration through a discussion of a curriculum for gifted students, the benefits of acceleration, a model for acceleration, guidelines for implementing an acceleration program, and ongoing issues related to the practice of acceleration.

Curriculum for Gifted Students

The literature is adamant: Gifted students are exceptional students who have three basic educational needs. They require the provision of a curriculum that is substantially and qualitatively differentiated; that is prescribed, planned, articulated, permanent, ongoing, and defensible; that is based on students' exceptionality; and that is predicated on the needs of each student. Gifted students require accelerated, enriched, and challenging learning experiences, with carefully planned, relevant enrichment and with content acceleration to the level of each student's ability. They also require counseling and guidance to foster cognitive and affective growth. Whereas most teachers and researchers involved with the education of gifted students agree that gifted students do require a differentiated curriculum, there is passionate debate concerning the form that this provision should take.

Counseling certainly is important for the social and emotional development of the gifted student and should be part of the framework for any program devised for gifted students.

Academic enrichment is worthwhile for most students and should not be offered to gifted students only. Relevant academic enrichment requires the provision of a program specifically designed for the individual. For gifted students, this will naturally entail advanced material and higher-level treatment of topics within their area of special aptitude, and the more relevant and excellent the enrichment is, the more it calls for acceleration of subject matter or grade placement later. Indeed, acceleration may well be the most appropriate form of enrichment.

The notion of academic acceleration is evidently contentious, with an enormous hiatus existing between what research has revealed and what most practitioners believe and do. The literature uniformly emphasizes that academic acceleration should form an integral component of a school's program for gifted students, complementing enrichment programs and provisions and following relevant enrichment. Resistance to academic acceleration, especially through concerns for the social and emotional development of the accelerated student, is not grounded in research. Clearly, educators need to be aware of the empirical research on the positive effects of academic acceleration. Moreover, the literature carefully points out that academic acceleration appears to be the best and most feasible method for providing a challenging, rewarding, and ongoing education that matches a gifted student's academic and intellectual ability and comes closest to meeting his or her educational, social, and emotional needs.

Whatever the status of the debate, if service delivery is predicated on a gifted student's precocious development and educational needs, then a differentiated curriculum should be challenging and educationally relevant and should be adapted by acceleration, enrichment, sophistication, and novelty. Such an eclectic approach to programming for the gifted will be employed within an integrative framework, adaptable to the cognitive and affective needs of the individual.

The issue may be placed in perspective by correctly noticing that a gifted student is *already accelerated* and that what is accelerated through academic acceleration is simply the student's progress through the formal school curriculum. The key point is that matching the curriculum to the student's abilities is not acceleration per se, but rather it is a developmentally appropriate teaching practice.

Types of Academic Acceleration

Grade skipping is but one example of academic acceleration. In practice, the range and types of academic acceleration also include early entrance to school, continuous progression, self-paced instruction, correspondence courses, combined classes, multiage classes, curriculum compacting, curriculum telescoping, extracurricular programs, mentorships, content acceleration, subject acceleration, credit by examination, concurrent enrollment, advanced placement (an American practice with few equivalents elsewhere),

early access to advanced-level studies while still at school, and early entrance to university.

Academic acceleration, therefore, refers to any of the ways by which a gifted student engages in the study of new material that is typically taught at a higher grade level than the one in which the child is currently enrolled, covers more material in a shorter time, and accordingly is seen to be *vertical* provision for gifted students. Implicit is the assumption that gifted students, who perform, or reflect the potential to perform, at advanced skill levels should be studying new material at levels commensurate with their levels of ability. Because a common characteristic of gifted students is their ability to learn at a fast rate, acceleration is seen to be a fundamental need of a gifted student and, in some form, should be an integral part of every gifted program.

A model for academic acceleration may refer to service delivery, whereby a standard curriculum experience is offered to a gifted student at a younger age or earlier grade than usual. Or it may refer to curriculum delivery, which involves increasing the pace of presentation of material, either in the regular classroom or in special classes. In either case, programs for academic acceleration allow the examination of content in greater depth, give access to subject matter at levels of greater conceptual difficulty, and should provide instruction that individually and explicitly matches the achievement levels, ability, interests, and learning style of the gifted student.

Benefits of Acceleration

Academic acceleration has several administrative benefits. It is a readily available and inexpensive educational option. It is a way of giving recognition for a student's advanced abilities and accomplishments. It increases learning efficiency, learning effectiveness, and productivity; it gives a student more choice for academic exploration; and it may give increased time for a career.

The report *A Nation Deceived* presents an excellent summary of recent research supporting the academic and affective benefits of well-administered acceleration. From this research come four important findings that are strong and clear and unequivocal.

First, acceleration is consistently and highly effective for academic achievement. No studies have shown that enrichment programs or provisions give more benefits to gifted students than methods of

acceleration. Academic benefits do arise from ability grouping accompanied by a differentiated curriculum, but the greatest benefit comes from academic acceleration. That is, accelerated gifted students, regardless of which form of acceleration is used, significantly outperform students of similar intellectual ability who have not been accelerated.

Second, there is no research to support the claim of maladjustment from acceleration. Despite the preponderance of evidence in favor of academic acceleration, concern about the social and emotional adjustment of accelerated students persists. This concern is cited by both teachers and administrators as the primary reason for opposition to academic acceleration. However, research finds no evidence to support the notion that social and emotional problems arise through well-run and carefully monitored acceleration programs.

Third, acceleration is usually effective in terms of affective adjustment. For many students, it removes them from difficult social situations and from unchallenging and inappropriate educational contexts. It exposes the student to a new peer group and, in fact, significantly increases the chances of a gifted student forming close and productive social relationships with other students. That is, academic acceleration goes a long way to meeting the social and emotional needs of the gifted student who uses it.

Fourth, a gifted student who is not accelerated when it is appropriate may well experience educational frustration and boredom; have reduced motivation to learn; develop poor study habits; have lower academic expectations, achievement, and productivity; express apathy toward formal schooling; drop out prematurely (there is at least some anecdotal evidence to support this); and/or find it difficult to adjust to peers who do not share advanced interests and concerns. That is, rather than expressing concern over potential socioemotional maladjustment arising from acceleration, teachers and administrators need to be concerned about the probability of maladjustment effects resulting from inadequate intellectual challenge.

A Model for Academic Acceleration

It is important to see academic acceleration not as a single intervention but rather as an ongoing, holistic, whole-school process necessarily involving the student, the student's caregivers, and his or her teachers.

Accordingly, Peter Merrotsy has developed an acceleration model that recommends six steps toward a better curriculum for gifted students: identification, communication, a negotiated curriculum, academic acceleration, access to advanced courses while still at school, and support.

Identification

Identification of a gifted student should imply that educational action will take place. It needs to be remembered that identification is notoriously unreliable, especially for gifted students from a background of disadvantage (e.g., low socioeconomic status or forced cultural minority status). That is one of the reasons why it is important to have a broad, inclusive curriculum and to have students involved in making decisions about their curriculum.

Communication

Each gifted student has a right to know the curriculum options and pathways available to him or her. Information about enrichment programs, extracurricular activities, meeting outcomes in alternative ways, high-level courses, senior courses, academic acceleration, and access to advanced-level courses while still at school should be clearly communicated to gifted students, and indeed to all students and their caregivers.

A Negotiated Curriculum

Gifted students are in a position to make informed decisions about their education. They should be actively involved in decision-making processes concerning their curriculum. Gifted students should be empowered to negotiate their curriculum.

Academic Acceleration

Academic acceleration appears to be the best and most feasible method for providing a challenging, rewarding, and continuous education which matches a gifted student's academic ability and comes closest to meeting his or her educational—intellectual, social, and emotional—needs. In order to provide acceleration options it may be necessary to change the organization of the school's curriculum and, in some cases, to change systemic policy.

Advanced-Level Courses

Access to advanced-level courses while still at school is an appropriate and natural progression for a gifted student who has academically accelerated. It is important to remember that an accelerated student could choose instead to study a greater number of secondary subjects, complete fewer secondary subjects but in greater depth, or take a year off, perhaps as an exchange student in another country. Whichever option is pursued, careful long-term planning, clear communication, and a negotiated curriculum are needed.

Support for Gifted Students

To help their intellectual, social, and emotional development, academically accelerated students need appropriate support, in terms of policy, administration, coordination of courses, enriched educational experiences, access to high-level courses, access to specialist teachers, tutors, counselors and mentors, and resources. In particular, gifted students from disadvantaged backgrounds, and from rural and isolated settings, need financial support so that they have access to resources and to educational experiences and opportunities enjoyed by others.

Guidelines for Acceleration

The *Iowa Acceleration Scale* offers a thoughtful and careful objective guide for whole-grade, academically accelerated progression and is supported by research and many repetition studies. There are four critical items: If a student's measured IQ is below 120, if a sibling is either in the same grade from which the student will accelerate or in the new grade to which the student will accelerate, or there is any antipathy by the student, then whole-grade acceleration is not recommended. School history; an assessment of ability, aptitude, and achievement; academic and developmental factors; interpersonal skills; and attitude and support by the school and family are then taken into account in order to give, or not give, as the case may be, a recommendation for whole-grade acceleration. If whole-grade acceleration is not recommended, then advice is available on the suitability of other forms of acceleration or on enrichment and extension programs.

Ongoing Issues

Two key issues need to be addressed worldwide if gifted students are to gain adequate access to a curriculum that includes options for academic acceleration. These issues need to be addressed to overcome the impact of social and cultural disadvantage and to give equity of access to appropriate educational programs for gifted students.

First, the findings of research concerning the academic and affective benefits of well-administered acceleration programs need to be accepted by educational administrators, communities, and teachers. System-organizational patterns of social grouping and the lockstep method of promotion constitute an effective barrier to the development of giftedness, suggesting the deep and urgent need for more flexible forms of school organization that ensure continuity of experience based on criteria other than age or years of attendance and that permit student progression based on individual development and performance.

Second, the end result or consequence of acceleration must be appropriately supported and managed by the education system. For example, with respect to advanced-level subjects studied while still at school, clarification is needed concerning equity of access, which can only be maintained through flexible forms of delivery and alternative modes of study; recognition that they constitute a formal component of secondary school studies, with continuity and articulation of curriculum; the status of secondary students who have completed advanced level units of studies, inter alia that they are still eligible for university entrance scholarships; and credit transfer.

ACCULTURATION

Acculturation is a complex process that includes those phenomena that result when groups of individuals having different cultures come into continuous firsthand contact, with subsequent changes in the original cultural patterns of either or both groups. The study of acculturation was originally of interest to the fields of anthropology and sociology, focusing on changes occurring at a group level. However, acculturation incorporates changes at the social, group, and individual levels. Later, other fields such as psychology examined acculturation at an individual level. The concept of individual acculturation is also referred to as *psychological acculturation*, which is explained as a change in attitudes, behaviors, beliefs, and values. In relation to acculturation, scholars have identified six areas of functioning that are directly affected by acculturation: language, cognitive styles, personality, identity, attitudes, and acculturative stress. Although acculturation is usually linked to cross-cultural relocations, as with immigrants and refugees, it may take place in numerous sociocultural contexts among a variety of groups. Acculturation is not restricted to those who embark on geographical movement; it can occur in stationary communities, such as in the case of indigenous or native people and ethnic groups in pluralistic societies.

Dimension of Acculturation

Whereas many scholars and research studies have focused on acculturation at a behavioral dimension, it is important to recognize that acculturation can affect other areas as well. Spoken language preference, television program preference, and participation in cultural activities are all ways in which acculturation can be experienced at a behavioral level. Additionally, acculturation can be experienced at a cognitive level, which may influence values and knowledge. The influence that acculturation has on the values may influence attitudes and beliefs about social relations, cultural customs and traditions, gender roles, and attitudes and ideas about health. Knowledge may be influenced by acculturation in the manner in which we recognize or know about culture-specific information, such as names of historical figures belonging to the culture of origin and the dominant culture and the historical significance of culture-specific activities. Lastly, cultural identity has been proposed as a dimension of acculturation. Cultural identity refers to the attitudes an individual has about his or her culture, such as feelings of comfort, pride, or shame toward the culture of origin or the host culture.

Theoretical and Conceptual Frameworks

Medicine and psychiatry had a major influence in the study of acculturation, and early theories of acculturation assumed a clinical viewpoint on matters corresponding to culture contact and change. Much of the early work on acculturation focused on anxiety occurring during cross-cultural transition.

Berry's Model of Acculturation

Most of the current literature uses Berry's model of acculturation to distinguish between the four models (assimilation, separation, integration, and marginalization) of acculturation.

Assimilation

The assimilation model of acculturation characterizes individuals that are highly acculturated; assimilated individuals strongly identify with the dominant or host culture, resulting in the loss of the original cultural identity. The assimilation model of acculturation has come to be known as *cultural shift.* Assimilated individuals that no longer identify with their culture of origin may behave in a manner that no longer reflects the behaviors of the original culture. For

example, assimilated individuals may no longer speak the native language, listen to native music, take part in native dances, or follow the native culture's dating process. Along with behavioral changes, assimilated individuals shift their beliefs, values, and attitudes to match those of the dominant or host culture.

Separation

In the separation model of acculturation, also referred to as *cultural resistance*, an individual will maintain a strong identification with the culture of origin and does not accept the behaviors, attitudes, beliefs, or values of the dominant or host culture. Although an individual may be presented with opportunities to acculturate, the individual consciously chooses to maintain an allegiance with the culture of origin. In this model the individual only displays the behaviors, attitudes, beliefs, and values of the culture of origin.

Integration

The integration model of acculturation, also referred to as *cultural incorporation* and *biculturalism*, is exactly what the term implies. The integration model is a merge and combination of two cultures: the culture of origin and the new dominant or host culture. Individuals in this model may successfully display behaviors, attitudes, beliefs, and values from both cultures. Individuals in this model identify with both cultures and have a level of comfort within both cultures.

Marginalization

The fourth model of acculturation is marginalization; the marginalization model is described as a rejection or nonacceptance of the behaviors, attitudes, beliefs, and values of both the culture of origin and the new dominant or host culture. It is important to keep in mind that a marginalized individual can maintain cultural competence with both groups and have marginal traits as well. Additionally, a degree of acculturation or identification with both cultures must occur before marginalization takes place.

Acculturative Stress

One potential outcome or response of acculturation is acculturative stress, which may result from differences in language, perceived cultural incompatibilities, and cultural self-consciousness. Some stress behaviors that have been associated with acculturation are anxiety, depression, feelings of alienation, and identity confusion.

It is important to note that some research has shown that acculturative stress is not related to the level of acculturation. Thus, one cannot assume that less acculturated individuals experience more acculturative stress than more acculturated individuals. Scholars have also suggested that acculturative stress can stem from the demands to maintain or learn one's cultural heritage while at the same time feeling pressured by the dominant culture to assimilate.

Adult Learning

Adult learning is a complex phenomenon. Although there are many commonalities between how adults

and children learn, development and change that take place across the life span play a definite role in understanding why adults learn, as well as how they learn. In educational psychology, an understanding of adult learning and the adult learner is crucial to a commitment to lifelong learning. Major challenges facing those who work with and study adult learners include questions about the extent to which knowledge is discovered or constructed and where one locates oneself in terms of focusing on individual and social aspects of learning.

History

In the early 1900s, the psychology of adulthood and aging received scant attention, largely due to the strong influence of psychologists such as John Watson, Sigmund Freud, and Jean Piaget, whose work emphasized the view that adulthood could be understood as simply an extension of development or learning in the early years of life. However, as psychologists such as Erik Erikson, G. Stanley Hall, Charlotte Bühler, and Sidney Pressey began to extend their theories and research to address the adult years, a greater understanding of the psychology of adulthood began to emerge.

Probably the first major study of adult learning was published by E. L. Thorndike and his colleagues in the 1928 book *Adult Learning*. As a seminal effort to provide empirical evidence related to learning in adulthood, these authors concluded that learning ability peaks at about age 45, rather than age 20 as previously believed. This study set in motion an effort to understand adult learning ability; this effort has continued to grow over nearly eight decades. Today, most of the research and writing on adult learning come from three fields: psychology, adult education, and gerontology. The field of psychology has offered a necessary, though not sufficient, foundation for understanding adult learning. Adult education and gerontology, through their professional literature, have also made important contributions to learning in adulthood. Although there is some overlap across these areas, each field brings a different framework and importance to the understanding of adult learning.

Participation in Adult Learning

One of the most extensively studied areas of adult learning relates to the nature of participation in adult learning. This involves three questions: Who participates in adult learning? Why do adults engage in learning? What are some of the factors that deter or limit adults from participating in learning? In 1965, William Johnstone and Ramon Rivera reported on a major national study of adult learning participation and found that 22% of all adults in the United States participated in some form of learning activity during the previous year.

Beginning in 1969, the U.S. National Center for Education Statistics began to collect data about participation in adult education. These studies have been conducted every several years and have offered insight into some major trends. Unfortunately, because different data collection procedures and definitions were used at different times, direct comparison across studies is not feasible. Nonetheless, it is possible to identify certain trends in participation.

Data from 2000–2001 indicate that 46% of all adults participated in some form of adult education activity during the previous 12 months. This compares with participation rates of 40.2% in 1995 and 33% in 1991. In terms of demographic breakdown, those in the 41-to-50 age group had the highest participation rate (55%), followed by the 16-to-30 and 31-to-40 age groups (53% each). Female participants outnumbered males (49%–43%), and in terms of race/ethnicity, Whites had the highest participation rate (47%), followed rather closely by African Americans (43%) and Hispanics (42%). As might be expected, those with higher educational attainment and income levels also had the highest participation rates. Finally, people who were employed during the previous 12 months had over twice as high a participation rate as those unemployed during the same period (54% compared with 25%).

The way in which participation is defined has an impact on the actual rates of participation. In the data cited in the previous paragraph, participation was defined as some form of adult education class. However, in the early 1970s, Allen Tough used a structured interview process to assess involvement of adults across the entire range of learning activities. In doing so, Tough found that as many as 90% of the participants in his study engaged in some form of learning activity over the previous year. Even more important is that he found the vast majority of learning projects (68%) were planned by the learners themselves, as opposed to a teacher/instructor, tutor, or nonhuman resource such as technology. Tough used the metaphor of an iceberg to illustrate what he found: Most

adult learning lies beneath the surface and is not easily visible to those who only study participation in organized courses or other activities. This finding played a key role in stimulating research on self-directed learning, which became one of the most widely studied topics in the adult education literature of the last decades of the 20th century.

To a large degree, participation in adult learning is linked to life transitions. These transitions often serve as "triggers" for adults to recognize that learning can help them negotiate such transitions. In today's world, job-related transitions (e.g., job loss, promotion, new responsibilities, retirement) are the most frequently identified reasons for participation. Other examples of transitions that can trigger the need for learning include family issues like marriage, divorce, and parenthood; health issues such as wellness, coping with a life-threatening illness, or being diagnosed with a chronic condition; enrichment opportunities such as leisure, art, or religion/spirituality.

One particularly influential study is Cyril Houle's *The Inquiring Mind*, which was originally published in 1961. Houle interviewed 22 adults deemed to be active learners and from these interviews, he identified a typology of orientations toward learning. Goal-oriented learners viewed learning as instrumental to achieving some other purpose; in other words, learning was seen as a means to another end. Activity-oriented learners sought out learning activities for their social value, as a way to meet new people and socialize. Learning-oriented adults were identified as those who engaged in learning for its own sake.

Many factors can serve as barriers or deterrents to participation in adult learning. These have been conceptualized according to several different categories. In essence, the major factors that limit participation are (a) reasons linked to the life circumstances of adults, which are often outside the control of the person, such as lack of time, money, transportation, and family responsibilities; (b) reasons related to institutional policies and practices that limit participation, such as scheduling of classes, information about offerings, limited offerings, and policies that discriminate directly or indirectly against adult learners; and (c) reasons related to attitudes and values of learners, such as low self-concept, fear of failure, negative past experiences, and lack of interest. In the 1980s and early 1990s, Gordon Darkenwald and his colleagues, Craig Scanlon, Thomas Valentine, and Elisabeth Hayes, reported on the development of several forms of the Deterrents to Participation Scale. This instrument has made it possible to isolate and identify many of the factors that contribute to nonparticipation in adult learning.

Intelligence, Memory, and Cognition

Central to the study of adult learning, especially in the realm of psychology and gerontology, has been the body of scholarship on the related areas of intelligence, memory, and cognition. Paul Baltes has described the aging mind as having both potentials and limits, resulting in age-related gains and losses. Whereas some areas of functioning show decline, other areas remain stable and, in some cases, show improvement with age.

To understand changes in intelligence, memory, and cognition over the adult life span, it is important to recognize that much of what has been reported is influenced by the types of research design that have been utilized. Cross-sectional studies measure different age cohorts at a single point in time. These studies make it possible to look at age *differences* on the variable(s) being studied; however, they do not accurately describe age *changes*. Longitudinal studies, on the other hand, measure the same cohort over time, making it possible to study changes that take place over time, but not cohort differences. Most of the early studies on intellectual functioning relied on a cross-sectional approach, and in such cases, researchers often incorrectly identified age-related declines when, actually, what they were observing were cohort differences. As is easy to picture, longitudinal research is difficult to carry out because it requires researchers who can envision and remain committed to a study over many years and even decades. Other problems with longitudinal studies are attrition of participants and instrument decay resulting from changes in the social context that can make earlier instruments irrelevant over time.

One way to minimize the limits of cross-sectional and longitudinal designs is to use an approach that combines both approaches in a single study. Here, longitudinal data are collected over time with a single cohort. During each measurement, however, a new cohort of younger participants is added. Eventually, this design will generate enough data to address age changes over time as well as cohort differences. Perhaps the most influential study of this type is the Seattle Longitudinal Study, developed by K. Warner

Schaie. Begun in 1956, with additional cohorts added every 7 years, the Seattle Longitudinal Study has focused on five mental abilities: (1) *verbal meaning*, which refers to the ability to understand ideas as expressed in words; (2) *spatial orientation*, the ability to visualize, manipulate, and perceive connections among objects; (3) *inductive reasoning*, the ability to recognize or make sense of new concepts and the ability to analyze and solve problems and situations; (4) *numeric ability*, which refers to understanding numbers and figures and the speed and accuracy with which a person can solve numerical problems; and (5) *word fluency*, involving ability to recall words in writing and speech. Basically, this study has presented evidence that in normal aging, there is little or no discernable decline in primary mental abilities until the mid-to-late 60s and this decline is slow until the 80s.

An area of debate related to intelligence in adulthood centers on whether intelligence is a general factor, as is typically defined in IQ tests, or whether there are different kinds of intelligence that account for a wide range of abilities. The view that there is more than one type of intelligence was introduced by Raymond Cattell and John Horn, who distinguished between *fluid* and *crystallized* intelligence. Fluid intelligence is a biologically based form of intelligence that is innate and involves reasoning ability. Crystallized intelligence, on the other hand, is largely dependent on education and experience. Thus, in this view, there is evidence that whereas fluid intelligence is characterized by age-related decline, crystallized intelligence, by building on past experience, typically increases over the life span.

In recent years, two theories have proposed that intelligence comprises multiple factors. Robert Sternberg has proposed a triarchic theory of successful intelligence, which holds that intelligence comprises a mix of analytical, creative, and practical abilities. The first of these is the more traditional view of academic intelligence. Creative intelligence centers on how well one addresses new and unfamiliar situations. Practical intelligence has to do with how effectively one is able to adapt to and solve everyday problems. A second approach to the multifactor view of intelligence is Howard Gardner's theory of multiple intelligences. According to Gardner, there are eight intelligences that address a wide range of abilities. These intelligences include linguistic, logical-mathematical, spatial, musical, bodily-kinesthetic, and two forms of personal intelligences that involve understanding oneself and others.

The eighth intelligence, naturalistic, has been added recently and is based on an understanding of the natural environment. The theories proposed by Sternberg and Gardner have relevance to adult learning because they recognize and value types of intelligence that extend beyond the more traditional IQ-based approach to intelligence. Because adult learning typically has a practical bent, emphasizing different kinds of abilities, the notion of multiple intelligence holds much potential for future research and practice with adult learners.

Memory is closely linked to intelligence. It involves the acquisition, retention, and recall of information. Although there are many schema for distinguishing among different kinds of memory, the distinction between short-term and long-term memory serves well to illustrate how information is retained and recalled in adulthood. *Short-term memory*, which typically covers a period of 10 to 30 seconds, can be further broken down into primary memory and working memory. Primary memory is more passive and involves holding information for immediate recall (e.g., remembering a phone number long enough to go to the phone and dial it or remembering information on a road sign when driving long enough to follow the desired direction). Working memory is more active and centers on the amount of information that can be held in memory long enough to perform some other operation on it. Research evidence suggests that whereas the changes in primary memory are small and gradual over time, there is a major decline in working memory with age. This decline has been attributed to a host of factors, including (a) a decline in mental energy that can result in overloading with increasingly complex tasks, (b) a weakened ability to use strategies related to working memory, and (c) a decline in speed of memory processing.

Long-term memory involves how facts are stored (semantic memory) and the ability to recall events from the past (episodic memory). Semantic memory is typically stable into the 70s and then declines gradually. On the other hand, episodic memory tends to decline with age although it is possible to compensate for some of this loss. Declines in long-term memory have variously been attributed to how material is acquired, how it is retrieved, and how fast it can be processed. At the same time, some researchers have suggested that memory training activities can help adults retain the ability to use knowledge, strategies, and skills.

Cognition involves all forms of knowing and awareness, including, but not limited to, information

processing, problem solving, perceiving, abstract reasoning, and judging. Much of the work on cognition in adult learning acknowledges the work of Jean Piaget as a starting point; however, because Piaget focused primarily on early development, subsequent work on cognitive development in adulthood has attempted to move beyond Piaget's original ideas. One model of cognitive development that is often adapted to the adult learning context is William Perry's intellectual development scheme. Based on data from male Ivy League college students, Perry found that as learners develop, they move from *dualistic* thinking, where "right and wrong" answers are presented by authorities, to *relativistic* thinking, where understanding the context is as important as the knowledge itself. An important response to Perry's scheme is the work of Mary Belenky, Blythe Clinchy, Nancy Goldberger, and Jill Tarule, who looked at "women's ways of knowing." They identified five categories of knowing, ranging from "silence," where women lack voice and are subject to what is expected from authority figures, to "constructed knowledge," where women perceive themselves able to create knowledge and to recognize all knowledge as contextual. This important study offered evidence of ways in which the experiences of women can differ from those of men.

A question that lies at the heart of cognition centers on whether knowledge is discovered or constructed. Whereas many views of cognition emphasize knowing as an internal process of uncovering knowledge that goes on within the individual learner, the literature on adult learning has increasingly focused on the social context in which learning takes place. This approach to understanding knowledge is often referred to as *situated cognition.* In situated cognition, knowledge cannot be separated from the context in which learning takes place. Thus, learning involves the construction of knowledge within the social milieu in which it occurs. Because it emphasizes learning in social context, situated cognition is characterized as having an inherently social or political element to knowledge and a connection to the importance of power in relation to cognition.

Theories and Concepts in Adult Learning

There is no single theory or model that explains adult learning. This should come as no surprise, as adults engage in learning for myriad reasons and in virtually unlimited settings. Adults become involved in learning for such wide-ranging purposes as work/career-related learning and training, literacy and basic skills development, earning credentials or degrees, social change or civic education, and personal growth, enrichment, and enjoyment. Adult learning takes place in such diverse settings as colleges and universities, public schools, business and workplace settings, health and human services agencies, churches, civic organizations, and government agencies, including the military. Although there is no single theory or model that can fully explain adult learning, there are nonetheless several theories or concepts that illustrate the scope of what is known about adult learning. Five of these are described in the following sections.

Andragogy

Andragogy is a concept that can be traced back to the 19th century. However, it came into prominence in adult learning during the late 1960s and early 1970s through the work of Malcolm Knowles. Knowles was looking for a framework to distinguish adult learning from learning in childhood (pedagogy). Later, Knowles suggested that pedagogy and andragogy are not limited to children and adults, respectively, but are more matched to the maturity and experience of the learner in a given setting. Though andragogy is sometimes described as a theory, it is probably more accurate to describe it as a set of assumptions about how people learn. According to andragogy, as learners mature,

1. their self-concept moves from being dependent to increasing levels of self-directedness;

2. the role of the learners' experience becomes an increasingly valuable resource, and adult learning is optimized when learners are able to tap into their experience;

3. readiness to learn in adulthood is increasingly based on real-life needs and situations;

4. there is a shift from learning for future application toward learning to address immediate needs;

5. intrinsic motivators become increasingly more important than extrinsic ones; and

6. before learning something, adults typically need to know why they need to learn it.

Although some critics have challenged andragogy because its focus is largely on the individual learner and does not directly address the social context in which learning takes place, andragogy retains an important place as a set of practices that have value when working with adult learners.

Self-Directed Learning

Closely related to the first assumption of andragogy, self-directed learning emerged in the early 1970s as one of the most systematic areas of research and scholarship on adult learning. Much of this interest grew out of the research of Allen Tough, which was mentioned earlier in this entry, on adults' learning projects. Subsequently, two individuals who have played a key role in developing this work, both through their own writings and through their many doctoral graduates, are Roger Hiemstra and Huey Long. Though there are many definitions, models, and conceptualizations of self-directed learning, it is essentially where the learners assume primary responsibility for and control over their learning. In 1991, Ralph Brockett and Roger Hiemstra synthesized ideas from several previous authors to present a model that describes self-direction as the product of two factors: the teaching-learning situation and internal characteristics of the learner. Out of this body of research, several ideas have emerged: first, self-directed learning is the most frequent way in which adults choose to learn; second, self-directedness has a strong connection to how learners feel about themselves as learners; third, several personality and social characteristics seem to have a connection to self-directedness; and finally, research on self-directed learning has probably contributed to a more holistic understanding of adult learners' potential.

Transformative Learning

Experience lies at the heart of adult learning. In most approaches to learning in adulthood, experience is acknowledged to be an important resource for the learner. However, it is not merely having an experience that matters; rather, it is the way in which the learner makes meaning of the experience and is changed by the experience that is important. In the 1970s, Jack Mezirow reported on a study of women who had returned to college. He described a process similar to consciousness-raising that took place for many of the women. Instead of simply acquiring knowledge, the experience of returning to college often resulted in a transformation that transcended the college experience and led to a redefining of the self. Initially, Mezirow referred to this process as *perspective transformation* and laid the foundation for a theory that has evolved over the ensuing three decades. Mezirow cited several key influences including Jürgen Habermas (critical theory), Roger Gould (psychoanalytic psychology), Paulo Freire (conscientization), and Thomas Kuhn (paradigm shifts). Through exchanges with various scholars who challenged aspects of Mezirow's theory, particularly those related to the emphasis on social change, Mezirow and these scholars refined the theory over time and began to use terms such as *transformation theory, transformational learning*, and *transformative learning* to describe this concept.

Transformative learning typically begins with a disorienting dilemma that makes it necessary for a person to examine existing assumptions and frames of reference. Examples of a disorienting dilemma include job loss, diagnosis of an illness such as cancer or diabetes, loss of a spouse or partner through death or divorce, or some sort of spiritual awakening. The dilemma, by its nature, redefines this aspect of one's life in a way that cuts across one's roles, responsibilities, and identity. Transformative learning involves a process of challenging assumptions in a way that helps one redefine oneself. An example of this would be an adult who returns to higher education and finds oneself immersed in study in a way that the person becomes socialized in an academic or professional field, and this new identity emerges as a vital part of who the person becomes.

In recent years, the literature on transformative learning has snowballed as various scholars have expanded on Mezirow's original ideas. John Dirkx, for example, has distinguished among four types of transformational learning. He describes Mezirow's view as a "cognitive-rational" perspective, which shares constructivist theoretical underpinnings with Freire's "emancipatory" approach but differs from Freire by emphasizing the process of reflection and rational thought. A third approach is the "developmental" perspective of Larry Daloz, which is holistic and contextually based and emphasizes how individuals negotiate developmental transitions in their lives. Finally, Dirkx describes a "spiritual-integrative" approach that extends beyond the rational approach to focus on feelings and images emerging from soul-based learning. The point here is that Mezirow's work is seminal to

understanding transformative learning, and subsequent work by various individuals, including work published in such sources as *Adult Education Quarterly* and the more recent *Journal of Transformative Learning*, demonstrates that this topic has assumed a central place in current scholarship on adult learning.

Humanism and Behaviorism

As with the field of educational psychology in general, humanism and behaviorism have held an important place in the conceptual foundations of adult learning. Humanism, with its view of human nature as basically good and the belief that individuals have virtually unlimited potential for growth, is particularly attractive to those seeking to bring out the best that adult learners can achieve. In humanistic adult education, Carl Rogers and Abraham Maslow are among the seminal thinkers. The humanist perspective underlies many of the tenets of andragogy and self-directed learning and is most often reflected in adult learning activities directed toward personal growth or improvement.

Behaviorism has also had a strong influence in the area of adult learning. With emphasis on reinforcement, learning for mastery, and helping people achieve competency in what is being learned, behaviorism has been especially influential in settings where performance and measurable outcomes are of primary importance. The influence of behaviorism is perhaps strongest in adult learning situations such as training in business and industry and adult literacy settings, where achieving measurable outcomes is deemed central to the success of learning. It can also be found where learning is designed to help people change specific behaviors, such as weight loss, smoking cessation, and substance abuse learning efforts.

Critical and Postmodern Perspectives

A major challenge to historically influential, learner-centered adult learning theories has, in recent years, come from critical and postmodern perspectives. Here, the focus is less on individual growth and development and more on issues of power and voice and the sociocultural context of learning. Sharan Merriam, Rosemary Caffarella, and Lisa Baumgartner have noted that major themes of these theories include race, class, and gender; power and oppression; and knowledge and truth. Because critical and postmodern theories emphasize the context in which learning takes place and the idea that

knowledge is socially constructed outside of the individual learner, these approaches are especially compatible with learning for social change. However, those who approach learning from critical and postmodern orientations tend to reject or minimize the importance of theories and research derived from a psychological orientation. For those interested in the psychology of adult learning, critical and postmodern theories pose a challenge in terms of the degree to which emphasis should be placed on individual and social dimensions of learning.

AFRICAN AMERICANS

This entry provides a summary of issues related to African Americans. It begins with a brief overview of

the history and geographical distribution of African Americans in the United States. This is followed by brief descriptions of attitudes affecting African Americans, including their attitudes toward the majority culture, religion and politics, racial identity, and African Americans in society. Next is a summary of the schooling experiences of, and educational outcomes for, African Americans and an overview of some of the major explanations for the achievement patterns of African American students. Despite decades of educational research, African Americans continue to have achievement levels that are substantially below their White and East Asian counterparts, on average, and this achievement gap has been the subject of considerable research in the field of educational psychology.

African Americans in the United States

At 12.3% of the population, African Americans are the second largest minority group in the United States, behind Hispanics who make up 12.5% of the U.S. population. Also commonly referred to as Black Americans, African Americans are still the single largest *racial* minority group in the country. Many Black biracial individuals and foreign-born Blacks also self-identify as African American. However, both of these groups are quite small, constituting less than 1% and 5% of the Black population, respectively. Black immigrants to the United States are from three primary regions: the Caribbean, Latin America, and sub-Saharan Africa.

In the early 1600s, some of the first Africans were brought to the United States as indentured servants. However, by the mid-1600s, the status of Africans in the United States had been changed to slaves. By the end of the legal slave trade in 1808, more than 500,000 Africans had been brought into the United States, primarily to work on the plantations in the southern states. Until the Great African American Migration (1910–1920), 90% of the African American population lived in the South, and less than 25% lived in urban areas. This early 20th-century migration of African Americans eventually yielded settlement patterns that are reflected in the United States today, with substantial concentrations of African Americans in the urban centers of the northeastern and midwestern United States.

The South still has the largest concentration of African Americans in the country, with more than 50% of the Black population. Nonetheless, African Americans constitute less than 20% of the South's population. African Americans make up about 11% of the populations in the Northeast and Midwest and about 5% of the population in the West. The top 10 residential areas for African Americans include the following metropolitan areas, in descending order: New York City, Chicago, Washington, D.C., Atlanta, Detroit, Philadelphia, Los Angeles/Long Beach, Houston, Baltimore, and Dallas. Although there have been declines in segregation over the past three decades, African Americans still live in highly segregated neighborhoods, and the metropolitan areas with the largest concentrations of African Americans also have the highest levels of residential segregation. Affluent African Americans also live in areas with high levels of residential segregation, and children experience the highest segregation levels at home and in school.

Attitudes Affecting African Americans

African Americans report a substantial amount of mistrust of Whites, and a majority of African Americans report experiencing racial discrimination at least once a year. African Americans report marked mistrust of the police and are more likely than other ethnic groups to believe in conspiracy theories. Thus, many African Americans believe that the majority culture does not want positive outcomes for their group. The increasing numbers of legal challenges to affirmative action, alongside media accounts of police brutality, reports of discrimination in housing and bank loans, and concerns about the disenfranchisement of Black voters in recent national elections, are seen as providing support for this hypothesis.

There is some evidence that African Americans' beliefs are not wholly without merit. Although overt negative attitudes toward African Americans have decreased in the broader society, recent research suggests that racist attitudes have become more covert over time and that aversive (unconscious) racism still plays a major role in the lives of African Americans. Thus, although fewer than 5% of Americans endorse negative stereotypes of African Americans, social psychology research reveals differential responses to African Americans in several circumstances. For example, in bystander intervention studies, individuals respond equally to Whites and Blacks when an emergency occurs *only if* they are the only witness; they are less likely to assist Blacks when there are multiple

witnesses. Also, people report the same number of negative characteristics for Whites and Blacks but report significantly more positive characteristics for Whites. Similarly, in evaluating job candidates, Black and White candidates with comparable weak and moderate skills are rated equally, but White candidates with strong skills are rated substantially higher than Black candidates with equally strong skills.

African American racial identity attitudes have also received considerable research scrutiny. Black racial identity was first conceptualized as a stage theory, with African Americans moving from an anti-Black stage to a pro-Black stage, with concomitant increases in self-concept. Recent theorizing conceives of Black racial identity as consisting of a set of multidimensional attitudes. Studies have provided support for several Black racial identity attitudes, including low salience attitudes, high salience attitudes, pro-Black attitudes, anti-Black attitudes, anti-White attitudes, and multicultural attitudes. Recently, researchers have demonstrated generalizable racial identity profiles in the population, although it is not yet clear how these will affect functioning. Several scholars have suggested that in the social context of the United States, many African Americans will have some minimal level of negative attitudes toward Whites.

Religion continues to play a major role in African American life, and the church has been one of the most important forces in the African American community. Estimates indicate that there are more than 60,000 Black churches in the United States, and African Americans have considerable membership numbers in several Christian and Islamic denominations. From a religious point of view, African Americans are generally conservative. However, on the political spectrum, African Americans are generally aligned with the Democratic Party. Initially strong supporters of Abraham Lincoln and the Republican Party after the American Civil War, African American political allegiance shifted as the Republicans compromised with southern states on issues of civil rights. For much of the past 30 years, more than 80% of African American voters have been affiliated with the Democratic Party, and the 109th Congress included 43 African Americans (1 senator and 42 representatives), all of whom were Democrats.

Educational Issues

African Americans comprise approximately 17% of the enrollment in public schools. However, they constitute about 20% of the students in special education, 30% of the students in vocational education, 23% of the students in alternative schools, and only 12% of the students in gifted and talented programs. African Americans also make up 10% of the private school enrollment. Overrepresentation in special education is greatest in the categories of mental retardation, developmental delay, emotional disturbance, deaf-blind, autism, and multiple disabilities. In contrast with the school population nationally, which is concentrated in suburban schools, more than 50% of African American students attend urban schools. On average, African Americans attend schools of lower quality with higher levels of segregation than other groups, even though it is 50 years after the *Brown v. Board of Education of Topeka, Kansas*, decision. In this case, the U.S. Supreme Court indicated that schools that were separate were inherently unequal. African American students report concerns about violence and the availability of drugs, alcohol, and weapons in the schools that they attend in substantially greater percentages than do other ethnic and racial groups.

One of the more persistent problems in the education arena is the achievement gap between African Americans, Latinas/os, and Native Americans on the one hand, and Whites and Asian Americans on the other. On average, African American students enter elementary school with weaker math, vocabulary, and reading skills than their White counterparts, even after controlling for parents' education levels, and this gap in achievement widens from Grades 1 to 12. Significantly fewer African American preschoolers and kindergartners can identify all the colors and alphabet letters, and twice as many African Americans in this age group are diagnosed with learning disabilities compared with their White counterparts. The event dropout rate (i.e., the percentage of students who dropped out of high school in a given year) for African American students is about 6%, and the status dropout rate (i.e., the percentage of individuals in the population from a certain age group who are not enrolled in school and have not earned a high school diploma) for African Americans aged 16 to 24 is approximately 13%. Dropout rates for African Americans declined substantially from the 1970s, but they stabilized in the late 1990s. In some urban districts, African American graduation rates are below 50%.

Data from longitudinal studies of school-age adolescents indicate that African American students miss

more days of school than the aggregate U.S. student population and have the highest suspension and expulsion rates. African American students also report spending more time watching television on weekdays and weekends. African American males are overrepresented in both incarcerated youth and youth on probation. These disparities are also reflected in both educational and occupational attainment. African Americans have lower college enrollment and graduation rates than do White and Asian students, and the percentages of African American workers decrease as one moves from clerical up to professional positions.

Explanations of African American Achievement Patterns

Several explanations have been advanced for African American underachievement, although it is likely that no single factor provides a complete explanation of this complex issue. Many of the initial arguments focused on environmental deficits. For example, it was assumed that African American homes were culturally deficient in ways that precluded academic achievement. However, differences related to academic achievement (e.g., quantity and quality of language in the home) were related more closely to class than to racial group. Deficits in the segregated schools that African Americans attended were also identified as a major concern, and one of the major legal accomplishments of the civil rights era was the *Brown v. Board of Education of Topeka, Kansas*, decision in 1954. This decision led to decades of desegregation plans by school districts, some of which are still in place.

Another long-standing argument has been based in biology and genetics—that is, African Americans have lower scores on measures of *g* (general intelligence) and consequently lower academic achievement. However, this explanation has been criticized for ignoring data on the increase in IQ scores over the past century (the Flynn effect), the reciprocal relationship between effective schooling and IQ, and the differential contributions of IQ to the variance in achievement across socioeconomic groups. There have also been suggestions that African Americans have different cultural styles than Whites and that there is a mismatch between Black cultural styles and the common methods of teaching in the school system. However, this suggestion has not been supported in empirical studies, in part due to the failure of researchers to adequately define and operationalize culture.

Socioeconomic status has also been put forward as a reason for African Americans' underachievement, as there is a moderate relationship between poverty and academic achievement. African Americans are one of the poorer groups in the United States, with 25% of African American adults and 33% of African American children living below the poverty line. In addition, more than 40% of the African American population live in households with annual incomes of less than $25,000, and African Americans comprise about 40% of the homeless population. Black males also have the highest unemployment rate, and only 12% of all African American households report incomes of more than $75,000. Although socioeconomic status plays a role, there are data indicating that the achievement gap is present at all socioeconomic levels.

Although there are consistent positive relationships between academic achievement and several psychosocial variables across racial and ethnic groups, including academic self-concept, academic self-efficacy, self-regulation, motivation, and future time perspective, there have been few studies of these constructs in African American populations, and the studies that exist have been of limited utility in explaining the achievement gap. African American students consistently report higher self-concept scores and educational and occupational expectations, despite lower academic achievement. There is a growing consensus that the motivation and future orientation of African Americans may be affected by the marginalized status of African Americans in society. African American role models in the public sphere are more frequently entertainers and athletes than academics.

Another set of explanations for African American achievement is psychosocial and implicates African Americans' collective or social identity, also referred to as their *reference group orientation*. Perhaps the best-known of these explanations is the cultural ecological theory proposed by the late educational anthropologist, John Ogbu. This model has been used to explain achievement differences across racial and ethnic groups around the world, including Australia, Great Britain, Japan, and the United Kingdom, and has also been used to explain achievement differences among racial and ethnic groups in the United States. In brief, cultural ecological theory suggests that one of the ways in which African American educational success is compromised is due to the group eschewing attitudes and behaviors that are conducive to educational attainment if the attitudes and behaviors are seen as "acting White."

Another explanation involving reference group orientation is the stereotype threat phenomenon proposed by Claude Steele, a social psychologist. This argument focuses on the pervasiveness of stereotypes in the populations and suggests that the strong negative stereotype about African Americans' intellectual capacities in the population can have a detrimental impact on African American performance in situations (e.g., academic evaluations of performance) where the stereotype is salient. Some researchers suggest that African Americans who care the most about doing well and have a strong sense of bonding to their racial group are potentially at greater risk for stereotype threat. Although much of the early research on stereotype threat was conducted with college-age samples, recent studies have demonstrated the negative impact of stereotype threat on school-age African Americans.

More recently, researchers have found that African American college students who are high in race-based rejection sensitivity are less likely to seek assistance in predominantly White institutions and more likely to be socially isolated, potentially decreasing their chances of persisting until graduation. Finally, researchers who study racial and ethnic identity in African Americans have hypothesized that some racial identity profiles may be more compatible with schooling outcomes than others, although there are limited data in support of this hypothesis. In addition, there are data that indicate that African Americans do not have to abandon their racial identity to be successful in school.

Several other theoretical perspectives implicate attitudinal and personal identity variables in academic performance. Self-worth theory suggests that students who are concerned with protecting their academic self-concept may *choose* not to study for examinations or engage actively in learning, thus providing a clear rationale for poor performance (i.e., not studying), rather than studying and taking the chance that they fail and be perceived as unintelligent. Another motivational perspective suggests that African American adolescents may have to choose between belonging to their racial group or being high achievers, leading many capable African American students to resist showing their true academic potential (i.e., *I can, but do I want to?*). Other researchers have reinvigorated the literature on teacher expectation effects by demonstrating that students can recognize differential behaviors by teachers toward high and low performers from the early elementary years onward. These findings suggest that the differential treatment of students perceived as more capable and less capable has direct effects on students' classroom functioning. The findings also indicate that minority students, who can recognize that they are members of stigmatized groups from the elementary school years, may be especially sensitive to the messages that teachers are communicating.

Health Disparities

As with the achievement gap, there are disparities in health between African Americans and White Americans across the life span. African Americans are either first or second with regard to infant mortality rates, low birthweight infants, and teenage pregnancies. African Americans also have the highest death rates in the United States, both generally and from specific causes such as heart disease, stroke, lung cancer, female breast cancer, and homicide. African Americans make up a substantial proportion of males (34.7%), females (60.5%), and children (61%) dying from AIDS. With regard to mental health issues, African Americans have less insurance and are also less willing to seek treatment, resulting in lower access to mental health care. The dearth of African American providers also contributes to an unwillingness to seek treatment.

Research Agenda

African Americans make up a substantial portion of the U.S. population. They are a group with a unique place in the history and current sociopolitical context of the United States, and their academic achievement relative to members of the majority culture represents one of the most intractable problems facing educational psychology. Educational psychologists need to develop a comprehensive research agenda on this issue. Although efforts to close the achievement gap continue apace, it is perhaps time to rethink the approach to African American achievement. Data from the 2005 National Assessment of Educational Progress indicate that Whites and Asian/Pacific Islanders in the fourth and eighth grades had higher reading achievement scores, 22 to 29 points higher, than their Black, Hispanic, and American Indian counterparts. Moreover, these scores have remained relatively unchanged for much of the past decade.

Beginning in 2002, the No Child Left Behind (NCLB) Act required school districts to disaggregate student performance data on the basis of demographic variables, including ethnicity, gender, race, and

socioeconomic status. One result of this requirement was to highlight the disparities in educational performance among groups at the local level, disparities heretofore seen only in national data. NCLB also proposes eliminating the achievement gap by 2014. However, there are still no explanations of the achievement gap that are accepted as definitive by large segments of the research community. Genetic, biological, environmental, demographic, and psychosocial explanations have both proponents and critics, and there are no studies in which combinations of all of these variables have been systematically examined.

Educational research indicates that effective interventions (e.g., *Sesame Street*) often have positive consequences for those who need them as well as for those who could have done without them. Thus, in the absence of interventions targeted specifically at and solely to African Americans, it may be difficult to *close* the achievement gap. However, the achievement gap between African Americans and Whites may not be the only issue that merits attention. An alternative perspective suggests focusing attention at the achievement levels that African Americans attain. From this perspective, educators should be concerned with ensuring that all African Americans attain at least basic proficiency in the core academic subjects and the skills to pursue advanced educational opportunities.

Research indicates that effective teachers make a difference in student performance and that the impact is cumulative over multiple school years, but it is not clear how these findings relate to African American student achievement. Nor is it clear how teacher education programs need to change to prepare teachers to not only be effective but also convey appropriate messages to African American students. Effective teacher training needs to counter the increased susceptibility of African American students to negative messages conveyed by teachers and help teachers counter aversive racism. More research is needed on the relationships between African American collective identity and psychosocial variables that are proximally related to academic achievement (e.g., self-efficacy, intrinsic motivation, and anticipation of success) and on the mechanisms that are effective in supporting these variables in African American students. Finally, researchers need to assess how much variance in African American student achievement is attributable to racial identity attitudes, oppositional identity, and stereotype threat, and which behaviors and attitudes are compatible with high academic achievement and African American ethnic heritage.

As should be clear, there are many questions that remain unanswered with regard to African Americans and schooling in the United States. Effectively addressing the educational issues related to African Americans will require a focused research agenda and collaboration between researchers and school districts with large numbers of African Americans. Educational researchers concerned with equity, and with African Americans specifically, have a challenging and worthwhile task that requires urgent attention.

AGGRESSION

Aggression is a common problem among schoolchildren and results in negative psychological, educational, and social outcomes for both aggressors and victims. This entry considers this aggression from both sides, that is, the side of the aggressors and the side of their victims. More specifically, it defines the terms *aggression* and *peer victimization* and reviews prevalence estimates of each. It also reviews the consequences of aggression for both aggressors and victims, as well as the antecedents or risk factors for each. This entry then moves beyond these generalities to discuss some of the subtypes of aggression and victimization. Finally, it offers some conclusions that can be drawn from the existing research and describes likely future directions for studying aggression.

Definitions and Prevalence

Aggressive behavior can be defined as any act that is aimed at harming another individual. More specifically, the study of childhood aggression often involves aggressive behaviors among peers, that is, children of similar ages (excluding aggression toward or from adults). Using this definition, attention is placed both on aggressors, who frequently enact aggression toward their peers, and on victims, who are often the targets of aggression by peers. It is important to note that some children may be considered both aggressors and victims; these aggressive-victims often have outcomes and risk factors that are distinct from children who are only aggressors or only victims.

Prevalence estimates of aggressors, victims, and aggressive-victims vary widely across studies because of different measurement strategies (e.g., reliance on children's self-reports or nominations of peers, teacher reports, observations) and criteria for classifying children (e.g., many studies define a child as a victim if they are targeted about once a week or more, but others will consider entire school years or lifetime incidents). Despite this variability across studies, it appears that about 10% to 20% of children can be considered aggressors, 10% to 20% can be considered victims, and 5% to 10% can be considered aggressive-victims. These prevalence estimates are remarkably consistent across countries, so it appears that aggression is a problem among schoolchildren worldwide. It is also worth noting that although these prevalence estimates would suggest that most children (50%–75%) are not directly involved as aggressors and/or victims, most children play some role in aggressive incidents, often serving as assistants or reinforcers to aggressors or as defenders of victims.

Consequences

The substantial prevalence of aggression and victimization is especially alarming when one considers the serious negative consequences of each. Aggressive children are often disliked by their normative (nonaggressive) peers and affiliate with delinquent peers who may solidify and expand the child's antisocial tendencies. Aggressive children are also often disengaged from school, either by their own choice or through negative teacher reactions, suspensions, and expulsions. These negative consequences of childhood are often exacerbated over time, leading to further delinquency, substance use, and school dropout during adolescence and to criminal behavior, poor marital relations, and unemployment/underemployment during adulthood. Of course, these associations are not perfect, and most aggressive children will discontinue, or at least decrease, their use of aggression with time and lead normal, well-adapted lives (in fact, there is evidence that most early adolescents will engage in some antisocial behavior, generally with few long-term consequences). At the same time, these long-term associations suggest that childhood aggression places individuals at increased risk for negative trajectories, and such behavior should certainly not be dismissed as "kids being kids."

As might be expected, victims of peer aggression suffer in numerous ways as a consequence of being abused. Victimization often leads to diminished

self-esteem and increases in internalizing problems (depression, anxiety, social withdrawal). Victims also tend to have poorer academic adjustment, including lower grades, disliking of school, and truancy; these consequences are intuitive if we imagine, as adults, how we would perform at work if we expected that someone might assault us on our next break. Victimization also leads to poor social outcomes, in the forms of having fewer friends, having friendships of poorer quality, and being disliked by most peers. This is unfortunate because the psychological consequences of victimization are diminished for victims who have good social support (e.g., friendships). Although the empirical evidence is limited, that which is available indicates that these negative consequences are long-lasting and persist as increased rates of depression and problematic romantic relationships, for example.

Children who are both aggressors and victims tend to suffer even more serious adjustment difficulties than children who are only aggressors or only victims. The additive risks alone of being both aggressive and victimized suggest negative adjustment, and these aggressive-victims do indeed appear to suffer the short- and long-term consequences of both aggressors and victims. Moreover, there is some evidence that these aggressive-victims suffer even worse outcomes than would be predicted by the additive effects of aggression and victimization. It is unclear if the dual roles of aggressor and victim are especially detrimental, or if the same risk factors that predict children becoming aggressive-victims (e.g., neurological deficits, histories of parental abuse) also contribute to their long-term maladjustment. Nevertheless, these children represent a special cause for concern.

Risk Factors

Given the prevalence and negative consequences of aggression and victimization, researchers have sought to identify factors that place children at risk for enacting and/or receiving aggression.

Predictors of aggressive behavior can be found in both home and peer contexts. Specifically, the home environments of children who enact aggression tend to be characterized by marital conflict and frequent aggression (e.g., domestic violence). Furthermore, aggression is predicted by parenting styles of inappropriate permissiveness or lack of monitoring of children's behavior, negative or rejecting behaviors toward children, and of physical punishment and/or

inconsistent discipline of children's behavior. In the peer context, research has shown that experiences of peer rejection and victimization predict increases in aggression, as do group social norms encouraging aggressive behavior and affiliation with aggressive and/or delinquent peers. It is worth noting that some of these peer-group risk factors for aggression are also consequences of aggression; thus, initial home environment may contribute to children's aggressive behavior, which results in peer relations that further solidify and exacerbate aggressive tendencies.

Victims of peer aggression are more often physically weak, suffer internalizing problems (i.e., depression, anxiety), and have lower self-concept than nonvictimized peers; each of these factors might make children less likely or less able to behave assertively or defend themselves, which may contribute to them being viewed as "easy targets" by potential aggressors. Similar to aggression, risk factors for peer victimization can also be found in both home and peer contexts. Parents who provide little support or responsiveness to their children's needs tend to have children who are more likely to be victimized by peers. Other parenting risk factors differ by gender; for instance, overprotectiveness and enmeshment predict victimization for boys (presumably leading to the failure to develop age-appropriate assertiveness), whereas coerciveness and threats of rejection are more predictive for girls (presumably leading to low self-concept). For both boys and girls, peer rejection, lack of friends, and engagement in antipathetic relationships (e.g., enemies) in the peer group place children at risk for victimization. Again, it should be noted that these peer-group risk factors are also consequences of victimization, suggesting the vicious cycle between peer victimization and poor peer relations in which children can become trapped.

Although aggressive-victims often have risk factors similar both to aggressors and to victims, there is also evidence of distinct risk factors. In the home context, rates of parental abuse and physical punishment are dramatically higher for aggressive-victims than for other children, and aggressive-victims tend to be rejected more and have fewer friends than either aggressors or victims. Although this entry has not focused on biological origins, it is worth noting that aggressive-victims have high rates of neurological deficits and attention deficit hyperactivity disorder (ADHD) as well. It is believed that these home and peer-group experiences (and possibly the biological risk factors) lead to hostile attribution biases (i.e.,

tendencies to interpret ambiguous behavior by others as hostile in intent), which contribute to aggressive-victims' behavior and further maltreatment by peers.

Subtypes

Despite the general findings regarding aggression and victimization reviewed above, not all acts of aggression are the same. Instead, aggressive behavior can be distinguished in terms of the form that it takes, the function that it serves, and the relationship context in which it occurs.

Forms

Historically, attention has been directed primarily toward studying overt forms of aggression, such as hitting, pushing, or teasing. More recently, however, researchers have realized that aggression also occurs in a more covert form. This type of aggression, variously called relational, social, or covert aggression, includes behaviors such as gossiping, spreading rumors, excluding the victim from groups, and manipulating relationships in a hurtful manner.

Overt versus relational forms of aggression and victimization differ according to age, sex, and context. Developmentally, physical aggression occurs most commonly during early childhood, and verbal forms emerge with increasing language capacities during early to middle childhood; in contrast, relational forms of aggression become more common during adolescence as knowledge of social structure, time spent with peers, and importance placed on peer relations all increase. The historical focus on overt forms of aggression has led to the notion that boys are more aggressive than girls, but more recent considerations of the various forms of aggression have shown that girls and boys are approximately equal in the amount of relational aggression enacted and in the amount received. Finally, there is evidence that different contexts support different forms of aggression, with overt aggression being more commonly enacted on playgrounds and similar areas without adult supervision, whereas relational forms, which might be more difficult for adults to detect, occur more commonly in classrooms.

Despite these differences, there exist high correlations between the two forms of aggression and the two forms of victimization—children who enact high levels of one form tend to also enact high levels of the other, and children who are the victims of one form tend to also be the victims of the other. This has made it difficult for researchers to detect distinct antecedents or consequences of the different forms of aggression or victimization. In other words, the empirical evidence does not provide a clear picture of whether overt versus relational forms of aggression have distinct origins or outcomes, nor whether the victims of these two forms have distinct risk factors or consequences.

Functions

Aggressive behavior can also be distinguished according to the function it serves. Most distinctions by function separate instrumental aggression from reactive aggression. Instrumental aggression (also called proactive aggression) is that which is intended to obtain resources or social status; for example, a child who pushes a peer in order to take a toy. Reactive aggression (also called defensive aggression) is a response, often in an angry, emotionally dysregulated manner, to a perceived offense or threat; for example, the child who throws a temper tantrum and hits a peer during a dispute.

There are two reasons that this distinction according to form is important. First, the two functions of aggressive behavior are believed to have distinct social-cognitive underpinnings. Instrumental aggression is believed (and there is empirical evidence to support this) to be driven by biases in the behaviors considered and evaluations of aggressive behaviors; for example, instrumentally aggressive children tend to believe that positive outcomes will result from aggression and value these outcomes obtained through aggressive behavior. Reactive aggression, on the other hand, is supported by biases in encoding and interpreting social information; for instance, reactively aggressive children tend to interpret others' ambiguous behavior as hostile. A second reason this functional distinction is important is because instrumental aggression and reactive aggression are differentially related to maladjustment. Although both are associated with delinquent behavior, reactive aggression is more strongly related than instrumental aggression to internalizing problems (e.g., depression, anxiety), ADHD symptoms, low prosocial behaviors, and low peer status. It is worth noting that aggressive-only children more often enact instrumental aggression, whereas aggressive-victims more often enact reactive aggression, although the overlap between subgroup classification and functions of aggression is far from complete.

Although the distinction between instrumental and reactive aggression has been important in the study of aggressive children, there has been little attention to how the function of the aggression affects the victims. It seems plausible that distinct characteristics might place children at risk for victimization via instrumental versus reactive aggression, but these distinct risk factors have not been identified. It is also unclear whether victimization by instrumental versus reactive aggression predicts greater maladjustment.

Relationship Contexts

Although researchers have typically considered the characteristics of aggressors and victims in isolation, there is an increasing awareness that aggression often occurs within specific aggressor–victim dyads (i.e., pairs in which a specific child aggresses against another specific child; for instance, Adam aggressing against Billy). For example, one group of researchers observed boys in small play groups and found that more than 50% of aggressive incidents occurred within just 20% of the dyads. These researchers also found that dyads in which aggression was evident on one day tended to be the same dyads that contained aggression on subsequent days. Together, these findings suggest the existence of aggressor–victim dyads in which aggression is especially frequent and persistent across time. The implication of this and related research is that a better understanding of aggression and victimization might be gained by considering the specific dyadic relationships of aggressors and victims.

Although there is very little research adapting this dyadic approach, the limited results demonstrate the importance of considering this relationship context. For instance, it has been found that aggression occurred more commonly within relationships based on mutual disliking (i.e., antipathetic relationships) than within friendships or acquaintanceships with neutral peers. Moreover, victimization within antipathetic relationships was more strongly predictive of maladjustment than was victimization within other relationships, suggesting that victimization within certain relationship contexts (i.e., antipathetic relationships) is more hurtful than victimization within other relationship contexts.

This focus on aggressor–victim relationships is relatively understudied, but it represents a fruitful approach for future research and consideration of occurrences of aggression. Several questions arise from such a consideration: Is there a differential in personal (e.g., physical strength) or social (e.g., popularity) power in aggressor–victim relationships, and does the amount of this power differential predict the form of aggression or outcomes for the aggressors or victims? To what extent are aggressor–victim relationships unidirectional or bidirectional in the enactment of aggression, and what characteristics of the individuals and relationship predict this directionality? Are aggressor–victim relationships relatively stable (i.e., the same aggressors targeting the same victims) or unstable (i.e., aggressors targeting different victims) over time, and what predicts this stability or instability? These questions represent just some that can be asked regarding aggressor–victim relationships; considering and answering these (and similar) questions represent important future directions for research and considerations for those working in applied settings.

Future Directions

Aggression is a common phenomenon in children's lives, resulting in serious maladjustment for both aggressors and victims. The evidence for this statement is conclusive, and the dismissal that such behaviors are just "kids being kids" is incorrect and arguably irresponsible.

Fortunately, research has identified several risk factors for aggression and victimization, providing a point of prevention or intervention for these problems. Unfortunately, translation of this research into application has been rather slow, and the existing intervention efforts have not proven as effective as would be desired. The refinement and widespread implementation of effective prevention and intervention of aggressive behavior represents an important task of educational psychologists (indeed, all professionals working with or studying children).

Part of the difficulty in developing effective interventions may be that for too long, aggression has been viewed as a homogeneous construct. Recent work has identified distinct forms and functions of aggression, as well as expanded consideration of the problem to one of an aggressor–victim relationship. Each of these approaches offers promise in better understanding and treating aggressors and victims.

Recognition and understanding of aggression and victimization holds much promise for reducing these problems. In schools where teachers are aware of school policies on aggressive behavior and have received training to deal with these problems, students tend to view

teachers as more approachable and willing to take action and, more importantly, experience lower rates of aggression and peer victimization. In other words, the first, and perhaps most important, step is simply in recognizing the problem and resolving to do something about it.

ALTERNATIVE ACADEMIC ASSESSMENT

Alternative academic assessment (AAA) is a class of procedures that are commonly used to assess student progress within the context of the curriculum to inform instruction. AAA is described as *alternative* because the measurement approaches are often used as an alternative to published norm-referenced and criterion-referenced tests. The latter types of published tests dominated the measurement of academic achievement and aptitude for most of the past 100 years. AAA emerged within the past 30 years as a potential supplement or replacement for more traditional procedures and instruments (e.g., Iowa Test of Basic Skills, Wechsler Individualized Achievement Test).

Many AAA procedures can also be described as *performance-based assessments* or *curriculum-based assessments (CBAs)*. These types of assessments typically rely on task demands and responses that are substantially similar to what might be observed during the process of instruction and learning. Production-type responses are more common than selection-type responses. That is, AAA procedures typically score the examinee's performance on the target behavior rather than a more convenient substitute. If reading is the behavior or interest, then the student's performance within the curriculum context is measured directly. For example, the examinee's oral reading rate might be measured while he or she reads aloud from a sample of curriculum and instructional materials. Similar procedures can be used in place of published tests that contain content dependent on curriculum and instructional materials or selection-type responses (e.g., multiple choice) that indirectly measure the target behaviors. Although there is a wide variety of AAAs, including CBA, curriculum-based measurement, CBA for instructional design, criterion-referenced curriculum-based assessment, curriculum-based evaluation, and informal reading inventories, most are characterized by procedures that measure production-type responses and stimulus content that are substantially similar to that of the curriculum and instructional materials. There are several advantages of AAAs, including efficiency of test development, administration, and scoring; the use of local norms; the utility for benchmarking and progress monitoring; and their utility within the problem-solving model.

Types

Curriculum-Based Assessment

Most AAAs fall under the umbrella of CBA. The fundamental characteristics of CBA include that it

(a) derives from, or is substantially similar to, the curriculum; (b) is linked to instruction; and (c) is used primarily to guide curriculum placement and instructional procedures. CBA procedures and instrumentation can be developed to assess skills within either a broad domain or a narrow domain.

CBA is divided into two subgroups: general outcome measures (GOMs) and subskill mastery measures (SMMs). GOMs are used to assess the level and rate of student achievement within a broad range of skills. GOMs are typically used to assess the achievement within the annual curriculum and instruction. A consistent set of procedures and instrumentation are used throughout the academic year. For example, mathematics computation in second grade might be assessed with tasks that span two-digit addition without carrying through four-digit subtraction with borrowing. The stimulus set and task demands are heterogeneous and representative of the annual curriculum. In contrast, SMMs are used to assess the level and rate of student achievement within a narrow range of skills and, usually, within a narrow range of time, which might be defined by an instructional unit. Procedures and instrumentation might change for each instructional unit so as to assess a specific and distinct set of skills that are aligned with the curriculum and instruction. For example, mathematics computation assessments might be narrowed to include only two-digit by two-digit subtraction without borrowing. The stimulus set and task demands are homogeneous and representative of the short-term instructional goal.

The variety of CBA procedures is broad. The following sections review a subset of available procedures. These include curriculum-based measurement, CBA for instructional design, criterion-referenced CBA, curriculum-based evaluation, and informal reading inventories. There are many other CBA procedures, which include end-of-chapter assessments that come along with curriculum materials. The selected procedures are a representative sample of those with the most prominence.

Curriculum-Based Measurement

Curriculum-based measurement (CBM) is a standardized assessment procedure that is used to index the level and rate of academic growth in four basic skills: reading, mathematics, written expression, and spelling. CBM is generally classified as a GOM because it is used to assess student achievement within the annual curriculum. It is defined as standardized procedure and not as a standardized test. This distinction is necessary because the instrumentation is not standard across applications.

CBM was developed by Stanley Deno and colleagues in the late 1970s through the mid-1980s. More than 200 research studies of CBM are published in peer-refereed journals, and technical development continues through the present day. CBM oral reading fluency (CBM-R) is the most prominent of the available procedures. In CBM-R, the student reads aloud for one minute as the administrator (usually the teacher) follows along on another copy of the passage. The administrator notes errors made and tallies up the number of words read correctly. This yields the student's reading rate, which is reported in units of words read correctly per minute. Error rates and accuracy are also reported sometimes.

CBM was designed to serve as an "academic thermometer" to monitor students' growth in four basic skill domains. The procedures are sometimes described as "dynamic indicators of basic skills." CBM is dynamic in that assessment outcomes are useful to evaluate the effects of instruction over the short term. Outcomes are useful to guide either summative or formative decisions. Summative decisions require one-time evaluations of the level of academic achievement. Formative decisions require ongoing evaluations of the level and rate of academic achievement, which are usually evaluated to estimate the effects of instruction. CBM is an indicator in that it provides a general assessment of academic health within each domain. That is, although CBM-R yields outcomes in words read correctly per minute, that level of oral reading fluency is useful to estimate the general reading achievement and predict performance on large-scale assessments (e.g., statewide tests). CBM targets basic skills in that there are procedures in each of the four fundamental basic skill domains (reading, writing, math, and spelling).

Formative assessment can inform intervention and determine the effectiveness of an intervention. Here is an example: Nick, a second-grade student was referred to the school psychologist for low CBM scores in reading. Nick reads 30 words correctly per minute, compared to the expected 60 words per minute by second grade. The school psychologist or teacher implements an intervention of paired reading for half an hour a day. The following week, Nick completes another CBM at 35 words per minute. Now

the discrepancy between Nick's score and the expected score has decreased, signifying that Nick is responding to the intervention. If the discrepancy continues to decrease, Nick will continue with paired reading until he reads at the expected second-grade level. Should the discrepancy remain the same or increase, the intervention will be modified until the desired level of growth is achieved.

CBA for Instructional Design

CBA for instructional design (CBA-ID) was developed to match the student to the appropriate instructional and curriculum level and focuses on individualizing instruction to ensure mastery learning of all students. A good instructional match maximizes student learning and engagement by fitting the student's needs. Research has found that students are most successful when they are able to respond correctly to material 93% to 97% of the time. This is called the instructional level. CBA-ID starts by finding the student's instructional level and then tests for areas of skill deficits.

CBA-ID has four steps. The first is to choose an appropriate passage for the student to read and test for the student's instructional level by asking them to read 20 to 30 randomly chosen words from the passage. If the student gets five or fewer words wrong, then he or she moves on to the next step. If more than five errors are made, then the student is retested in a passage at a lower level. The second step requires the student to read the passage. As the student reads, the examiner records the student's errors. Afterward, the student is asked questions about the passage to assess how well the student comprehends what he or she read. The last two steps of CBA-ID are to use the assessment information to match the student to appropriate reading instruction and curriculum. Progress monitoring continues as the student is instructed and necessary changes are made.

Criterion-Referenced CBA

Criterion-referenced CBA (CR-CBA) is similar to CBA-ID in that it was developed to determine appropriate instructional materials and strategies. The methods differ, however, in that CBA-CR determines an acceptable level of performance by comparing student scores to a locally normed sample of average peers. Students are tested on items from the curriculum in

order of easy to difficult within a reading series. The teacher or examiner constructs reading tests by using 100-word passages from the beginning, middle, and end of the reading series. Students are tested across 3 days on nine passages; three from the beginning, middle, and end each. As the student reads, the examiner records student errors and then calculates the student's accuracy level (percentage of words read correctly across the entire 100-word passage) and rate of reading (the product of accuracy and 60 divided by total seconds it took the student to read the passage). Next, the student is asked six comprehension questions. Finally, the median scores for the 3 days of assessment are summarized. Assessment decisions are made based on the student's performance compared to the mastery criteria.

Curriculum-Based Evaluation

Curriculum-based evaluation (CBE) is used to determine the student's general whereabouts in the curriculum to identify specific areas of skill deficit. Administration begins with survey level assessment to identify if the student's performance meets expected goals. The initial survey level assessment is developed by sampling a broad domain from the curriculum. In the case of reading, for example, broad skills such as decoding and comprehension are tested. If the results show that the student has a deficit, a skill-specific criterion-referenced test is administered. This second test focuses on specific skills such as segmenting words, rhyming, intonation, and other reading-related subskills. Results are used to adapt instruction to the student's needs.

Informal Reading Inventories

Informal reading inventories (IRIs) are similar to CBE in that they identify specific subskill deficits. There is much variance among the increasing number of published IRIs; however, most follow a typical assessment method. First, the student is asked to read from a graded word list. Depending on the student's accuracy, he or she moves up or down a grade level in word lists until the student's instructional level is found. The definition of this level varies among IRIs but usually falls around 90% words read correctly. Second, the student reads a passage from his or her instructional level. As the student reads, the examiner records the student's errors, or *miscues.* This yields

the student's accuracy and reading rate. Next, the miscues are grouped into categories like omissions, substitutions, low fluency words, and repetitions. Attention is also paid to the types of words that are miscued. This allows the examiner to identify specific areas of weakness. For example, a student may struggle with words with a silent *e*. IRIs determine not only which level of curriculum to place students in but also specific areas of weakness.

Advantages

Efficiency

The administration of AAAs is quick (taking as little as 1 minute) and requires few resources. Items can be developed easily by teachers and taken right from the curriculum. Furthermore, AAAs require little training to administer or score. Also, because they are flexible and can be designed to assess specific domains of academics, AAAs allow school psychologists and other educators to test specific assessment questions rather than routinely test across a broad number of academic domains.

Use of Local Norms

Performances on AAA are often interpreted with reference to local normative data. Local norms are developed from samples of student behavior using AAA procedures. Local norms directly represent the school district population, academic goals, and outcomes rather than the performance of students nationwide. They also decrease the likelihood of bias in decision making because they are representative of student age, grade, race, educational background, and socioeconomic status.

Another advantage of local norms is that there is greater overlap between what is taught and what is tested. Districts have the flexibility to design comparative data based on the specific curriculum. This high teaching-testing overlap yields more meaningful data on student progress. CBM-R is the most common alternative academic assessment that is used to create local norms. In many districts, students complete CBM-Rs in the fall, winter, and spring.

Benchmarking

Benchmarks are sometimes used to evaluate student performance with a criterion-referenced interpretation.

Both benchmarks and local norms are used as referents to evaluate whether students are making adequate progress to achieve expected long-term goals. For example, if students are expected to read 60 words correctly per minute in CBM-R by spring of first grade, then by winter, it is likely they should read 45 words correctly per minute. A student who scores significantly lower than the winter benchmark is identified as at-risk. The student is then given additional help so that by spring, he or she achieves the targeted level of performance. Benchmarking provides information that will help in determining which students are at risk and should be monitored more closely. To this end, benchmarking is also a vital component of prevention. It allows educators to identify and fix small problems before they become larger.

Utility Within the Problem-Solving Model

Historically, students were placed in special education based on their scores on large norm-referenced tests (the "test and place" model). An intelligence score below a certain criterion resulted in a label such as "learning disabled." The student was then matched to special education services based on that label, and the problem was viewed as an inherent trait within the student. Beginning in 2001, a shift has occurred away from the traditional model and toward the problem-solving model.

The problem-solving model focuses not on traits of the student but on environmental and situational factors that can be modified to increase student outcomes. The problem-solving model follows these steps: identify the problem, measure the severity of problem, explore possible interventions, implement an intervention, and measure progress in hopes that the student can be successful in the general education setting. The problem-solving model is a circular process, as progress is constantly being monitored and interventions are adjusted accordingly. The problem-solving model does not rely on unproven inferences as does the traditional model. Hypotheses are continually tested and monitored with AAAs. Thus, decisions are evidence-based because student data are considered when creating and modifying interventions.

AAAs provide the necessary tools to implement the problem-solving model, as they efficiently assess student performance and can be repeated often. As the

popularity of the problem-solving model increases, so does that of AAAs.

Utility for Progress Monitoring

Alternative academic assessments not only identify students who are at-risk but also determine if intervention efforts are successful. Because they are efficient and drawn directly from the curriculum, AAAs can be used repeatedly to monitor student progress and response to intervention. Repeated measures provide not only the level of performance but also the student's rate of growth. This allows educators to determine if the student is making adequate improvement or not. If the intervention does not produce the desired rate of growth, then changes are made to the intervention.

AMERICAN EDUCATIONAL RESEARCH ASSOCIATION

The American Educational Research Association (AERA) is the primary professional organization for educational psychologists. Founded in 1916, it is concerned primarily with encouraging and promoting scholarly work, including research and writing, that is associated with the educational process. Another important role that AERA plays is the dissemination of information related to its mission.

The 25,000 members of the organization are a collection of scholars and practitioners from diverse fields, well represented by the 12 divisions that the organization hosts (see the following box for the names of these divisions).

American Educational Research Association Divisions

Administration, Organization, & Leadership (Division A)
Curriculum Studies (Division B)
Learning & Instruction (Division C)
Measurement & Research Methodology (Division D)
Counseling & Human Development (Division E)

History & Historiography (Division F)
Social Context of Education (Division G)
School Evaluation & Program Development (Division H)
Education in the Professions (Division I)
Postsecondary Education (Division J)
Teaching & Teacher Education (Division K)
Educational Policy & Politics (Division L)

Each of these divisions (and members often belong to more than one) carries on its own activities, including the election of officers, the publication of a newsletter, the granting of awards for outstanding research by graduate students as well as professionals, and a listserv so that members can remain abreast of new developments.

In addition to its 12 divisions, AERA also sponsors special interest groups (SIGs), which are less formal than divisions but serve many of the same purposes. As is apparent by the list (see the following box), SIGs are of a much more specific nature than are divisions. As of 2006–2007, there are 42 SIGs and each SIG has a program of awards as well.

AMERICAN INDIANS AND ALASKA NATIVES

American Indians and Alaska Natives (AI/AN) are persons descended from the original inhabitants of North,
Central, and South America and the Caribbean. Those who occupy what is now the State of Alaska are referred to as Alaska Natives. The colonization experience of Alaska Natives is originally seeded in Russian occupation, but their experience mirrors that of the tribes in the lower 48 states. As a group, tribal peoples of the Continental United States are referred to herein as First Nations persons. In the United States, there are more than 560 federally recognized nations and an untold number of non–federally recognized groups. These First Nations are culturally distinct and include populations speaking more than 300 discrete languages. The 2000 U.S. Census Bureau reported First Nations

persons of full or partial decent comprise roughly 1.5% of the total U.S. population, accounting for slightly more than 4 million persons. In 1987, Russell Thornton estimated the population had exceeded 72 million in 1492. By 1800, according to Thornton, the number had been reduced by roughly 95% as a result of disease, warfare, and oppression. Systemically, the fields of education, mental and behavioral health, and medicine are products of this historical context. A conscious endeavor to comprehend the First Nations experience is essential to any professional working with this population. Sadly, this process is generally not undertaken during academic professional training. Following is a discussion of the historical implications for First Nations persons in relation to their inter- and multigenerational experience. Cultural resiliencies and treatment implications are considered, as well as best-practice frameworks.

Historical Context

It is widely recognized that Columbus was not the first European to make contact with the Americas. Regardless, this discovery myth persists and permeates presumptions about the First Nations in many fields, including educational psychology. The consequences of Columbus's contact, however, have been significant. One of the earliest outcomes of his arrival was the enslavement of Indigenous inhabitants. European-modeled slavery directly contributed to the mass disruption of many tribes' gender role structures and systems of government. Tribes were impacted differently by slavery depending upon the era in which they interacted with the newcomers; however, contact generally magnified intertribal disputes and fostered a divide-and-conquer stance toward the First Nations. Perhaps at the height of irony, some First Nations even adopted a pseudo-European model of slavery after years of intermingling with those of European and African descent. When slavery was abolished in the United States, all but one slave-holding tribe extended full tribal citizenship to newly freed slaves. This entitled former African slaves the right to acquire land, tribal representation, and protection under tribal laws, therefore requiring the U.S. government to deal with such persons as African Indians. Slavery historically correlates with the introduction of blood quantum as a measure of ethnic identity and belongingness for First Nations persons, a concept formalized within the federal reservation system. The impact of European-modeled slavery in the Americas is complex and ongoing, and its understanding changes the completion of what has traditionally been perceived as a Black and White element of American history.

More devastating than slavery to the First Nations and their ways of living was the impact of disease post-1492. Of the many diseases brought to the Americas by Europeans, the greatest killer was smallpox. This disease followed trade and warfare routes and struck in repeated waves of pandemic, decimating the vulnerable immune systems of the First Nations. Thornton has identified scores of other diseases introduced by Europeans, including measles, the bubonic plague, cholera, several variations of venereal disease, and rare forms of influenza and respiratory disease. Likewise, the introduction of African slaves to the Americas saw the presentation of diseases such as malaria and yellow fever. Thus, the clear conqueror of the First Nations was the repeated exposure to diseases by which they were decimated at a horrific and incomprehensible rate.

As the First Nations population decreased and the number of Europeans increased, the competition for land and resources became a focal point for conflict. Warring European groups, such as the French and English, capitalized on traditional rivalries between some First Nations tribes and forged alliances with opposing tribes. Most alliances were relatively short lived and dissipated once the First Nations were no longer of benefit to their White allies. Tensions soared between Europeans and the First Nations as the United States of America declared its independence. With the cultural integration of European tools of war such as the horse and firearms, conflicts between the two groups became more intense and lethal. The United States adopted a strategy of treaty making and entered into agreements with First Nations tribes, promising to cease hostilities in return for land concessions on the part of First Nations persons. Between the years of 1775 and 1890, hundreds of treaties were signed between the First Nations and the United States, though few were honored by the United States for any meaningful length of time in their original form. Tribes continued to be encroached upon, and armed conflict flourished. The U.S. Bureau of the Census indicated in 1894 that more than 53,500 American Indians were killed in wars between the United States and First Nations tribes. This number is likely in the hundreds of thousands if one includes the numbers who died as a result of Indian against Indian warfare as an outcropping of some tribes' alliances with the U.S. government.

Acts of genocide add to First Nations casualties. Genocide includes acts intended to destroy (partly or wholly) a national, ethnic, racial, or religious group, including killing or causing serious bodily or mental harm, instituting living conditions highly correlated with death, preventing births to the group, and/or forcibly transferring children of one group to another. Both the U.S. government and its citizens committed acts of genocide. Often cited are incidents of germ warfare via infected blankets given to some First Nations; however, it is difficult to determine how many deaths may have occurred in this fashion, if any. Clear examples of genocide against the First Nations are found in incidents such as the hunting down and murder of First Nations persons during raids in the California and Texas territories, where American Indians were commonly viewed as less than human. In addition, scores have died as a result of harsh governmental policies that fostered little chance for sustenance and survival. It is difficult to discern where acts of warfare end and genocide begins. Many of the incidents of the Indian Wars once described as *battles*, such as those at Sand Creek and Wounded Knee, have now come to be known as massacres of First Nations persons instead.

Though resistance continued on a relatively small scale after 1890, that year is generally recognized as the end of the Indian Wars. As the First Nations fell under the control of the United States, relocation and removal were increasingly used to deal with "the Indian problem." Removals persisted for decades following 1890, and nearly every First Nations group was affected by relocation as the United States strove to accommodate its encroaching settlers. These forced moves separated individuals from their families, communities, and traditional lands upon which entire ways of life and worldview systems resided. During marches, tribes often endured harsh treatment and conditions, cutting to the core of the human capacity to make meaning of what was being endured. High rates of mortality were recorded, and historical writings reveal the emergence of modern-day disorders such as *refugee syndrome* and *concentration camp syndrome*, conditions currently recognized as manifestations of posttraumatic symptoms. The First Nations were faced with repeated and persistent stress, trauma, loss, and grief to which they were forced to respond. A core source of resilience and coping was found in the pan-Indigenous value system and worldview. The First Nations turned to their spiritual leaders for

guidance and hope. As the U.S. government sought continually to manage its Indian problem, it resorted to an apartheid approach of diplomacy—the reservation system. Tribes were generally removed from traditional lands and given dominion over a smaller tract. The life on reservations was often appalling, with starvation, violence, and death all too frequent. The changes First Nations persons faced were pervasive and affected their mental, behavioral, and physical health. The impact of this paternalistic treatment by the United States persists, and First Nations persons continue to struggle with the implications.

As American Indians and Alaska Natives fell under the increased control of Whites, acculturation and assimilation pressures mounted. This is particularly true in respect to the education of First Nations youth. The boarding school era is recognized by First Nations scholars and professionals as the most destructive period in U.S. Indian policy. During the 1800s and 1900s, First Nations children were removed from their homes, as early as age 5, and sent to Christian mission and Bureau of Indian Affairs schools for European-oriented education with a focus on assimilation into White culture. Probably the most famous school was Carlisle Indian School in Pennsylvania, the first off-reservation government-sponsored boarding school. The school was established in 1879 by Henry Pratt, a veteran of the American Civil War and the Indian Wars, whose goal was the complete assimilation of the First Nations. Pratt's motto was "Kill the Indian and save the man." This stance toward Indian education continued well into the 1900s, and First Nations youth were trained in domestic and labor tasks via the school's *outing system* that prepared them for their place in White society. Children were not allowed to practice traditional culture and were prevented from speaking traditional languages and wearing traditional hairstyles and clothing. First Nations youth were forced to practice Christianity and forbidden, often in the face of physical threat, to practice their traditional religions. Children were subjected to harsh punishment in the military fashion of the schools' educational philosophy, and many children endured emotional, physical, and sexual abuse. This era saw generations torn from their traditional, holistic ways of learning and knowledge acquisition and reared instead in a militaristic, institutional setting virtually devoid of the caretaker bonds now recognized as fostering healthy attachment and relationships. The full effect of the boarding school era continues to be

examined in respect to both the costs to and the resiliencies drawn upon by First Nations persons.

As failed Indian policies became apparent to the mainstream citizenry, the political tide turned from paternalism to that of fostering self-determination. One failed attempt at this goal was that of Termination. Termination policy was instituted in the early to mid-1900s to defederalize tribes, dissolving their political status as sovereign nations within the United States and thus their trust relationship with the government. The naive intention was to end governmental paternalism, but what was actually instituted was another form of forced assimilation. First Nations persons were subjected to state laws, and tribal lands were converted to private ownership by former tribal members. First Nations persons were forced to own land individually versus communally and were often forced to utilize it for farming, though virtually no provisions were made for helping tribes obtain the needed capital for such an endeavor. Much of the land made its way to White owners when the Indigenous owners were forced to sell it to support themselves and their families. Virtually overnight, First Nations persons in as many as 100 reservations, bands, and rancherias became *not Indian* as defined by mainstream law. Termination policy has resulted in significant identity struggles for many American Indians and Alaska Natives, as one's ethnicity is defined by another, seemingly at whim and on a continuous basis. An additional outcome of Termination was the mass removal of First Nations persons from reservation areas to urban areas with the promise of employment, education, medical care, and improved quality of life. Unfortunately, what many First Nations families found was poverty and an increased sense of marginalization, as they were now separated from their tribal communities.

The 1960s marshaled in an era of societal and political change in the United States. Self-determination for the First Nations emerged as a priority, and the coming decades saw increased emphasis on fostering sovereignty. The Indian Civil Rights Act of 1968 was passed, prohibiting states from assuming jurisdiction over federally recognized tribal peoples and their lands under Public Law 280. The Indian Education Act of 1972 was an initial effort to require specialized training for educators in an effort to produce and fund cultural competency and to stimulate local attention to First Nations issues. The Indian Self-Determination and Education Assistance Act of 1975 encouraged tribes to assume control over federally funded programs and

provided additional funding. The Indian Child Welfare Act of 1978 was a response to the massive removal and institutionalization of First Nations children via foster care, adoption, and detention in juvenile facilities. First Nations children were to be preferentially placed with First Nations families under the jurisdiction of tribal courts. The American Indian Religious Freedom Act of 1978 recognized the right of First Nations persons to practice their religions and required federal entities to adopt policies of noninterference. In 1988 the Indian Gaming Regulatory Act further defined tribal sovereignty. Also in 1988, Section 5203 of the Tribally Controlled Schools Act added to the intent of the Indian Civil Rights Act and fully repudiated Termination policy. The Native American Graves Protection and Repatriation Act of 1990 acknowledged the profound impact that centuries of objectification have wrought upon the First Nations. The remains of First Nations persons and their burial sites were recognized as sacred, and scores of the deceased were released from museums around the world and returned for proper rites among their peoples. Finally, the Indian Arts and Crafts Act of 1990 furthered the de-objectification of First Nations peoples and helped turn the tide of cultural acquisition.

The 21st Century

Today, the U.S. Census Bureau reports that the First Nations are a young population as compared with other ethnicities, with just less than half living on a reservation or federal trust land and a little more than half living in urban areas. First Nations persons are overrepresented within the numbers of negative social and economic indicators of disparity. Though rates vary widely between tribes and geographic regions, the First Nations find themselves with many of the most disparaging statistical measures of societal success. Economically, they lag behind other ethnic populations, having high poverty and unemployment rates and disproportionately low educational opportunities and graduation rates at all levels. Physical health disparities include high rates of diabetes and heart disease. Mental and behavioral health disparities include depression, posttraumatic stress disorder, and alcohol abuse for the First Nations as a whole.

First Nations children and youth receive disproportionately low levels of prenatal care as compared with other populations. They are exposed to alcohol in utero at higher rates and thus suffer rates of fetal alcohol

syndrome disproportionately. As a group, First Nations youth endure disproportionate rates of diabetes, obesity, inner ear infection, cancer, and toxin exposure. The lack of accessible culturally competent health care compounds the negative impact on First Nations health. Suicide and homicide are among the top 10 causes of death for First Nations youth ages 5 through 14 years, and loss and grief follow this young population as a whole, given the historical and persistent struggles with which it is faced. Emerging public health issues for the First Nations include high rates of pregnancy for young women and girls who have insufficient access to prenatal care, escalating rates of sexually transmitted disease (including HIV/AIDS), and an explosion of gang involvement, even in reservation areas.

Health, Resiliency, and the Balance Way

The disparities and impacts of colonization with which many First Nations struggle is best conceptualized through an Indigenous worldview. The situation then becomes historically bound and has been framed by First Nations elders and tradition keepers as transcending time in a spatial fashion and experienced both individually and collectively. Thus, historical events are experienced in real time by individuals and their communities. Healing occurs through communal support and recognition of suffering and ritual interventions. In this way, suffering is acknowledged by the individual and his or her support system, and assessment, diagnosis, and treatment occur via a vehicle that emphasizes both individual and group strategies. First Nations scholars and clinicians advocate for an intervention framework that recognizes the inter- and multigenerational nature of the loss, stress, and trauma to which American Indians and Alaska Natives are exposed. Such a framework is congruent with the First Nations concept of time and healing and draws upon the use of traditional concepts and strategies.

Assessment, Diagnosis, and Treatment: First Nations Values and Ancient Knowledge

Despite the breath of diversity within the First Nations population, pan-cultural values and worldview perspectives exist. One commonly held view is that of time as cyclical and spatial versus linear, as conceived by the mainstream. Emphasis is on process rather than product. Contextual space or environment is often closely tied with experience and thus with healing. The First Nations see all as connected, whether celestial, elemental, mineral, fauna, animal, or human. Relationships are not compartmentalized along blood lines but rather viewed as broad connections that invoke relational roles. For example, siblings and cousins may be seen as equivalent relationships for an individual, and both will be referred to as brothers or sisters. In this spatial worldview, conceptions of wellness and ill health, life and death are grounded in the idea of keeping balance internally and with the world around one's self, and moving from one time-space domain to the next, respectively. Traditional healers utilize place (e.g., sacred locations) and integrate the help of other elements (e.g., plants, animals) to aid in helping the individual rebalance. Given the value placed on process and the cyclical nature of existence, all human experiences are held as important. Events such as dreams, visions, and premonitions are integrated into the healing process and not pathologized in the vein of mainstream psychology. Traditionally, there is a broad acceptance of difference and individual diversity, and thus a strategy of relative noninterference exists. Persons are supported through change individually with a healer and/or communally, and they are encouraged to find their own path to meaning and balance, utilizing their own gifts and strengths in doing so. This idea of individual difference and noninterference is quite divergent from mainstream thinking and is particularly evident in mainstream socially constructed concepts, such as that of gender or sexual orientation/preference. Pan-culturally, First Nations persons traditionally view gender as discrete from sexual orientation, identity, and preference.

Given the historical context within which the fields of psychology and education have developed and the current statistics the First Nations face, it is clear that pervasive cultural competence is lacking in assessment, diagnosis, and treatment of this population. Stereotyping, stigma, and discrimination pervade the intervention process with the First Nations and are highly correlated with low rates of contact and retention within the helping professions. Clinicians must consider the possibility of institutional distrust on the part of First Nations clients. Accommodation must be made for cultural differences present between the client and the clinician as well as between the client and the system of service. Language can pose a particular roadblock to intervention, regardless of whether the client speaks English as a second or a first language. Previous generations pass down the cultural worldview housed in Indigenous languages. First Nations

languages are relational and descriptive in nature and do not accommodate compartmentalization as English does. Most Indigenous languages provide an understanding of the world as either animate or inanimate, not living or dead. Gendered language too is relatively nonexistent in the fashion of Western-mainstream languages. A close examination of popular standardized assessment and diagnostic tools quickly reveals their inability to competently accommodate First Nations clients. The vast majority of such tools, including the *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision) *(DSM-IV-TR)*, have been developed through a linear, White mainstream worldview, and few have been standardized or explored in relationship to their use with the First Nations.

Learning: Indigenous Science and Knowledge Acquisition

American Indians and Alaska Natives have had sophisticated systems of hypothesis testing and knowledge acquisition for thousands of years. This knowledge has persisted in oral, written, pictorial, and ritual traditions. Unfortunately, systemic racism, discrimination, and ignorance have all played a role in the perpetuation of the stereotype of First Nations science as a proto-knowledge, a less sophisticated form of Western-mainstream constructs. It is in this atmosphere that First Nations persons are educated by mainstream institutions of learning. Acculturation and assimilation pressures are significant for First Nations children in educational settings and persist through higher education.

Preschoolers may encounter difficulties adjusting to their new setting and its demands. Traditionally, First Nations youth are raised with close attention to attachment building and may share a bed with their primary caretaker(s), may be breastfed until they are 3 or 4 years old, and may enjoy the attention of multiple caretakers regardless of blood ties. Children entering elementary school are often encountering mainstream culture for the first time and can be shaken by the shift in worldviews within which they must function. Boys may be ridiculed for keeping their hair traditionally long, and all youth are subject to defending themselves against the onslaught of holidays and practices celebrated in school systems that may be Christian-focused or U.S. nationalist. Language issues can be a particular challenge, and children may be required to shift from an experientially based traditional educational focus at home to a more linear, prescribed learning style in the educational setting. By middle and high school, First Nations youth often confront the full force of stereotyping and discrimination, as well as the aforementioned risk factors. They may encounter existential crises, struggling to integrate traditional spiritual beliefs with mainstream culture. The risk for internalized oppression is great, as teens strive for identity and self-preservation. A traditional adolescent may attend a school that promotes stereotyping and demeans the spiritual worldview of First Nations persons via Indian mascots or the promotion of, and forced participation in, Christian-based activities. This pressure mounts as those First Nations youth who do graduate from high school attempt to make their way to college. College students may have to travel great distances from their tribal communities and lands, deepening existential struggles. In higher education they find few First Nations mentors, little funding, and can struggle greatly to resolve the rift between their traditional worldview and that of the Western mainstream.

Indigenizing the Mainstream

Best practices with American Indians and Alaska Natives mandate the integration of traditional knowledge, practices, community, and tradition keepers. Successful strategies and programs are individualized and recognize the potential for divergent worldviews and diversity within this group. Legitimate ways of knowing and healing are held within the First Nations culture and have been utilized for thousands of years to educate and heal this group. The educational psychologist will find a wealth of helpers within the community's natural supportive structure. Elders, traditional healers and mentors, extended family, and many others can be of assistance for case conceptualization and treatment. Traditional knowledge and values can be found in a group's original instructions (creation story) and provide a useful framework for conceptualizing a client's struggle, as well as his or her ethnic identity. Finally, policies that support the integration of understanding between the mainstream and First Nations may be supported by educational psychology as socially just objectives that promote healing and understanding for both groups.

ANDROGYNY

Androgyny is a term derived from the Greek *andras* (άνδρας—man) and *gyne* (γυνή—woman) referring to either the absence of any distinguishing masculine or feminine traits, as in the Hijras of India, or the combination of both masculine and feminine characteristics, whether spiritual, psychological, or physiological.

Most Western cultures presume a binary opposition between male and female. In the 1950s, June Singer revived a mystical interest in androgyny, reconciling the "masculine" and "feminine" aspects of a single human, restoring the balance between what Jung called *animus* and *anima.* Like Mircea Eliade and Carl Jung, Singer treated androgyny as archetypal, in which the divided self yearned for the complete reunion of male and female. This understanding of androgyny as a metaphysical ideal was implicit in shamans or deities like Buddha, Shiva, Kuan Yin, and Elohim. Even so, Singer believed that the sexes were naturally differentiated: that males are generally aggressive, dominant, hard, and logical, and women are passive, compliant, soft, and intuitive.

In 1974, Sandra Bem published the Bem Sex Role Inventory (BSRI), a self-test listing 20 socially desirable female traits, 20 socially desirable male traits, and 20 considered to be neutral. Male traits included "forceful," "analytical," and "self-sufficient"; female traits included "sympathetic," "loyal," and "compassionate"; and neutral items included "truthful," "sincere," and "friendly." Scores revealed the respondent's self-reported possession of socially desirable, stereotypically masculine and feminine personality characteristics. An individual who received high scores for both female and male traits was defined as androgynous, whereas one with low scores in both was described as undifferentiated. Gender traits had little correlation with the ascribed sex of participants. Like Singer and Jung, Bem believed that people who had androgynous psychological traits were the most effective and well-functioning individuals in society.

At this time, Constructivism claimed that gender was socially constructed and could therefore be changed at will. Resistance to gender binaries and heterosexuality took the form of transvestitism, or performances as drag queens or drag kings. Kate Bornstein, having performed as a cross-dressing performance artist and encouraged the self-construction of "who you are," used surgery to change herself in 1998 to a "male-to-female lesbian transsexual" but has now settled into being neither male nor female, a gender outlaw.

To describe a born male as "lesbian" indicates some of the conceptual change required by this new gender fluidity, but it did not necessarily accommodate androgyny. A medical category, gender identity disorder, was created to describe those who felt incompatibility between their felt identity and their anatomy. Improvements in surgical processes made it possible to normalize anatomies as normalized male or female, and medical research sought to explain sex "transgressions" (gender identity disorder, cross-dressing, or homosexuality) physiologically in order to remove blame and effect a "cure." A few transsexuals, like female-to-male Jamison Green, rejected such normalizing "cures" and accepted their androgynous status to the extent of having hormone treatment but not requiring a surgically constructed penis or denying their past.

Despite a relatively low level of sexual dimorphism in humans, Charles Darwin had naturalized the sex binary in *The Descent of Man* by referring to naturally selected sex differences between male and female in gonads, sex organs, body mass, amount and placement of body hair, intelligence, psychological traits such as aggression, and child-rearing practices. But he tended to overlook the high amount of androgyny in the natural world, for instance, in worms and snails. About 30% of the fish species on a coral reef start out as males and end as females, or vice versa, or are both male and female at the same time. Could humans be naturally androgynous?

In 1993 in *Bodies That Matter*, Judith Butler argued that even though we construct gender, our material bodies sometimes prevent us from conforming to social norms. Earlier in *Gender Trouble*, she

claimed that drag queens in their "queer performativity" demonstrate resistance to being required to "perform" normal dichotomous roles of male or female which they do not feel. The existence of physically androgynous humans challenges those dichotomies at an even more profound level.

Anne Fausto-Sterling estimates conservatively that 1 in 1,000 persons is born with androgynous physiological features. Previously called *hermaphrodites*, they are now medically defined as *intersex*, a term, like *androgyny*, applied to any person with characteristics determined as neither exclusively male nor female, or combining features of both. The most common cause of so-called sexual ambiguity is *congenital adrenal hyperplasia*, an endocrine condition in which the adrenal glands produce unusually high levels of virilizing hormones. In genetic females, this leads to an appearance that may be slightly masculinized (large clitoris) to quite masculine. Another form of intersex is *androgen insensitivity syndrome*, in which people born with masculinizing Y chromosomes do not develop male morphology. Other physiological androgynes show chromosome variations such as 47XXY, 45XO, or mosaics. Far from being revered as complete or ideal persons, such anatomical androgynes are usually classified as male or female sex at birth and surgically or hormonally transformed into either male or female in childhood, with remaining variations of the male-female binary seen as transgressive.

Bem and Fausto-Sterling argue that the danger of perpetuating the male-female binary lies in the fact that cultural roles and norms remain dictated by males and highly polarized male values. The placement of the androgyne at the center of our understanding of physical and cultural humanness and our acceptance of complex combinations of male and female defuse current hegemonies.

ANXIETY

Anxiety is a common mental health concern facing many Americans today. In 1997 Thomas Huberty defined *anxiety* as a unique emotional state characterized by feelings of distress and tension about real or anticipated threats that may manifest in cognitive, behavioral, or physiological patterns. Anxiety can have devastating effects on individuals, as it can interfere with their learning and social and emotional development. In this entry, general information about anxiety is presented. Common features found among the anxiety disorders, types of anxiety disorders, and etiological factors underlying anxiety disorders are discussed. Prevention and intervention strategies are covered.

Components of Anxiety

Anxiety is a complex emotional state and may involve and influence multiple domains of an individual's functioning. Specifically, an individual may experience

cognitive, behavioral, and physiological effects. Common cognitive symptoms of anxiety include excessive worries, concentration difficulties, and memory and attention problems. Anxiety may also be manifested through such behavioral symptoms as motor restlessness, difficulty sitting still, and attempts to escape or avoid anxiety-provoking stimuli or situations. Finally, anxiety also includes physiological symptoms, such as muscle tension, increased perspiration, rapid heartbeat, headaches, and stomachaches.

Anxiety as a Unique Emotion

Anxiety is a unique emotion as it can be viewed in both a positive or negative light. A slight amount of anxiety can be helpful and facilitate an individual's performance, whereas too much anxiety can be debilitating and hinder one's performance. In small amounts, anxiety can serve as a motivator and lead to optimal performance in school, work, sports, or other areas in an individual's life. For example, a student can become slightly anxious before a major exam. The slight anxiety felt can motivate the student to study for the exam and do better because of the time spent preparing for the exam. In contrast, high levels of anxiety may interfere with the student's ability to concentrate, process information, or retrieve information from long-term memory. Under these circumstances, the student is less likely to perform his or her best on the exam.

Anxiety can also alert an individual to a potential danger. The fight-or-flight response, also referred to as the acute stress response, involves the activation of the sympathetic nervous system in an emergency situation. The individual will respond to a threatening or dangerous situation by fighting or fleeing. Thus, many believe that anxiety serves as a survival mechanism and protects the individual from harm.

Besides its positive and negative aspects, anxiety can be viewed as a normal indicator of development. During the normal course of development, individuals experience fears and anxieties, but the specific fears and anxieties experienced vary as a function of age. Moreover, there is some evidence to suggest that the number of specific fears and anxieties decrease with age, whereas others suggest that the number of specific fears and anxieties remain the same across the life span. Sources of anxiety for infants include loud noises, strangers, and novel stimuli, and for toddlers, separation from major attachment figures and imaginary creatures. Children fear large animals, darkness,

and natural events, and adolescents fear social alienation. Sources of anxiety for adults include natural events, injury, and financial issues. Most individuals experience these age-specific anxieties and fears, which are mild and transient in nature.

Prevalence of Anxiety and Comorbid Conditions

Prevalence rates of anxiety in community samples are difficult to estimate, especially given the fact that internalizing disorders, such as anxiety, are often difficult to observe and identify. Prevalence estimates for clinical levels of anxiety in children, young and middle-age adults, and older adults range from 5% to 19%, 6% to 8%, and 9% to 11%, respectively. In general, the prevalence of anxiety disorders has been found to increase with age in the child and adolescent population, decline during the young and middle-age adult years, and slightly increase in the older adult years. Gender differences have also been found in the literature. Specifically, females typically report more anxiety symptoms than do males. However, it remains unknown at the present time whether this gender difference is due to females actually experiencing more anxiety symptoms than males or whether females are simply better able to recognize and report their symptoms of anxiety than are males. On the other hand, overall, more females than males are believed to suffer from an anxiety disorder. However, the gender ratios differ based on the type of anxiety disorder diagnosed and the age of the individual. Despite this variability and the need for further research with regard to prevalence rates among different ages and genders, it is clear that anxiety continues to be a major problem for individuals of all ages and one that can potentially lead to significant difficulties within multiple domains of functioning.

Anxiety disorders have high rates of comorbidity with other disorders. The rate of comorbidity between anxiety and depressive disorders may be as high as 55% to 65%. Speculation as to why these rates are so high is that both anxiety and depression share a similar trait known as negative affectivity, or emotional distress. Negative affectivity includes such affective states as worry, self-dissatisfaction, and sadness. High comorbidity rates may also be due to a sequential link between anxiety and depression, with anxiety serving as an early precursor to a depressive disorder. Comorbidity rates are also high between different types of

anxiety disorders. It is not uncommon for an individual who has one anxiety disorder to be diagnosed with another anxiety disorder. Other common comorbid conditions include substance use disorders and disruptive behavior disorders, such as attention deficit hyperactivity disorder, oppositional defiant disorder, and conduct disorder.

From a trait model perspective, anxiety is viewed as a stable personality characteristic. Without treatment, anxiety disorders may persist. Approximately 45% to 65% of individuals diagnosed with an anxiety disorder do not show remission of symptoms. However, approximately 35% to 55% of individuals do show remission, but many who show remission develop other disorders, especially other anxiety disorders. Anxiety disorders interfere with the social and emotional well-being of individuals. If individuals are still in school, academic development may be impaired. For adults, work productivity may decline and unemployment may increase.

Developmental Precursors or Etiological Factors

Different theories exist about the development of an anxiety disorder. The three most popular models used to explain the development of an anxiety disorder are the biological, behavioral, and cognitive models. Biological explanations of anxiety focus on genetics, neurotransmitters, differences in structural regions of the brain, abnormalities in the immune system, and behavioral inhibition. Genetics is believed to play a role in the development of an anxiety disorder. Genetic influences account for approximately 30% to 35% of the variance in anxiety in most cases, suggesting that anxiety is moderately inheritable. The neurotransmitter gamma aminobutyric acid (GABA) has received some attention as a possible risk factor in the development of an anxiety disorder. GABA may increase excitatory responses to real or perceived threats, or it may fail to send messages to inhibit these responses. Perturbations in the hypothalamic-pituitary-adrenal axis indicate structural brain differences in individuals with an anxiety disorder. Behavioral inhibition may be another possible etiological factor. Behavioral inhibition characterizes a child's temperament. Children with this type of temperament are shy and exhibit inhibited behaviors in response to novel stimuli. These individuals are also highly physiologically reactive to such stimuli.

Behavioral explanations for the development of an anxiety disorder focus on learned behaviors. According to behaviorists, anxiety is a learned behavior that is acquired and maintained through a combination of classical and operant conditioning, operant conditioning alone, or modeling. From a classical and operant conditioning perspective, anxiety problems result when a neutral stimulus, such as a large dog, is paired repeatedly with an aversive stimulus (i.e., an unconditioned stimulus), such as a loud noise, to produce an unconditioned response, such as a startled reaction. Through repeated pairings with the unconditioned stimulus, the neutral stimulus becomes a conditioned stimulus, and this conditioned stimulus will produce a conditioned response. In other words, the presence of a large dog will result in a startled response without the loud noise being present on a regular basis. The conditioned stimulus (i.e., a large dog) will then be avoided, and by avoiding the conditioned stimulus, an individual's anxiety is reduced. The avoidance behavior demonstrated by the individual in response to the large dog is an example of operant conditioning. In operant conditioning, the stimulus, task, or situation feared is maintained by a negative reinforcement contingency. The feared stimulus, task, or situation is avoided, and the avoidant behavior is maintained because it reduces the individual's anxiety. In modeling, the individual observes the behavior of significant others in response to aversive stimuli, tasks, or situations. When significant others exhibit avoidance behavior and anxiety in response to aversive stimuli, the individual learns to model these behaviors. Exposure to similar aversive stimuli, tasks, or situations will produce similar behaviors.

The cognitive approach to anxiety disorders assumes that distorted cognitions are responsible for symptom manifestation. According to cognitive psychologists, individuals who have an anxiety disorder or experience high levels of anxiety exhibit threat-related attentional and interpretative biases. These individuals attend to threat-related stimuli, and they interpret ambiguous or neutral stimuli as threatening.

Common Features of Anxiety Disorders

Although different types of anxiety disorders exist, according to Michael Telch, Jasper Smits, Matt Brown, and Victoria Beckner, there are some common features across these different disorders. Common features

include escape and avoidance behaviors, chronic worry, attentional hypervigilance, faulty threat perception, and sympathetic activation. Individuals with an anxiety disorder try to avoid or escape from stimuli or situations that make them anxious, and they constantly worry about current and future events. These individuals attend excessively to cues that they perceive as threatening. The excessive attention given to these cues is referred to as *attentional hypervigilance*. Faulty threat perception is another common feature found among individuals with an anxiety disorder. These individuals erroneously perceive situations as threatening. Sympathetic activation is also a core feature found among individuals with an anxiety disorder. Activation of the sympathetic nervous system producing physiological changes in the body occurs in individuals with an anxiety disorder when there is no real or potential threat. Physiological changes experienced by these individuals in the absence of a real or potential threat may include accelerated heart rate, muscle tension, and increased perspiration and respiration.

Types of Anxiety Disorders

The *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision) *(DSM-IV-TR)* has identified 15 types of anxiety disorders, including generalized anxiety disorder, separation anxiety disorder, specific phobia, social anxiety disorder, obsessive-compulsive disorder, posttraumatic stress disorder, acute stress disorder, panic attack, panic disorder with and without agoraphobia, agoraphobia without a history of panic disorder, anxiety disorder not otherwise specified, anxiety disorder due to a general medical condition, and substance-induced anxiety disorder. Generalized anxiety disorders, phobias, obsessive-compulsive disorders, panic disorders, and posttraumatic stress disorders are the most common types of anxiety disorders.

Although there are several types of anxiety disorders, each involves an excessive degree of worry or fear about certain stimuli, situations, or events, which significantly interferes with an individual's normal state of functioning. Generalized anxiety disorder is characterized by a chronic, excessive, and uncontrollable degree of worry about a variety of events or situations, such as friends, family, school, work, or the future. Symptoms of generalized anxiety disorder include fatigue, irritability, restlessness, muscle tension, and difficulties with concentration and sleep. Another common anxiety disorder, specific phobia, is characterized by an extreme

and irrational fear in response to a specific stimulus, such as animals or insects (e.g., dogs), aspects of the natural environment (e.g., storms), blood (e.g., viewing blood or receiving an injection), situations (e.g., being in small spaces), or other stimuli (e.g., loud sounds or costumed characters). This worry must be present for at least 6 months and may lead to symptoms in children such as crying, clinging, tantrumming, dizziness, shortness of breath, and fainting.

Like a specific phobia, social phobia is associated with particular circumstances and must involve symptoms present for at least 6 months. An individual with a social phobia experiences extreme worry regarding social situations. The individual may worry over or fear the possibility of ridicule, humiliation, or embarrassment in social situations, such as speaking in class or conversing with peers. Individuals with a social anxiety disorder may attempt to avoid or escape social behaviors, and they often have poor social skills. These individuals may also experience symptoms such as trembling hands or voice, perspiration, muscle tension, and blushing.

Obsessive-compulsive disorder involves obsessions (recurrent or persistent thoughts or worries that intrude on, and interfere with, an individual's normal functioning) and compulsions (repetitive behaviors, rituals, or practices in which the individual engages to provide relief from, or comply with, the obsessive thoughts or worries). Common obsessions and compulsions in children include contamination (hand washing), safety (checking), preoccupations with orderliness and symmetry (ordering, aligning), and counting or touching rituals. Individuals with an obsessive-compulsive disorder may feel embarrassed by their compulsions and may experience difficulties related to concentration, preoccupations, and perfectionist tendencies.

Posttraumatic stress disorder refers to stress or worry experienced by an individual following a traumatic event (such as a serious injury, death, or catastrophic event). The individual reexperiences the event (via flashbacks, nightmares, or images), as well as the accompanying physiological arousal, and may attempt to avoid stimuli associated with the event. Following the event, the individual may feel helpless, fearful, agitated, or disorganized and may experience hypervigilance, irritability, and difficulties with concentration or sleep. These symptoms must be present for at least 1 month following the traumatic event. If symptoms are present for less than 1 month, then an acute stress disorder may be present. Similar to posttraumatic stress

disorder, acute stress disorder also results from witnessing or experiencing a traumatic event. Symptoms include reexperiencing the event and the accompanying physiological arousal; however, these symptoms are present for no more than 1 month.

A panic disorder refers to recurrent and unexpected panic attacks that are followed for at least 1 month by concern about, or consequences of, having another attack and/or a change of behavior related to the attack. Panic attacks develop abruptly, often last for approximately 10 minutes, and involve symptoms such as heart palpitations, sweating, chest pain, dizziness, fear of dying, feelings of detaching from one's body, and feelings of losing control. If the attacks become more frequent, the individual may come to fear experiencing a panic attack in public places, and develop agoraphobia (fear of public places) as well. However, agoraphobia may also develop in the absence of, and without resulting from, a panic disorder. In these cases, individuals may avoid public situations, such as being in a crowd or traveling in a train, and may experience symptoms of panic in these situations.

Separation anxiety disorder is an anxiety disorder commonly found in children. Separation anxiety disorder refers to excessive and unrealistic worry in response to separation from home or a caregiver. Children with separation anxiety disorder may experience nightmares with separation themes, headaches, stomachaches, or nausea. These symptoms must be present for at least 4 weeks. Separation anxiety disorders tend to decrease with an increase in age. That is, this type of anxiety disorder is common during the childhood years but declines during the adolescent and adulthood years.

Anxiety disorders may also result from external factors, such as a general medical condition or substance use. Finally, for individuals who experience symptoms of anxiety, but whose symptoms, duration, or impairment do not meet the criteria for a specific disorder, a diagnosis of anxiety disorder not otherwise specified (NOS) may be appropriate.

Anxiety Disorders in Children and Adolescents in School

Many children and adolescents who either have been diagnosed with an anxiety disorder or have high levels of anxiety experience difficulty in the school setting. Students with anxiety disorders or high levels of anxiety have more difficulty learning new material,

receive poorer grades, and do not perform as well on standardized and classroom tests. These students may struggle in core courses such as reading and math. They are also more likely to repeat a grade and drop out of school.

Besides experiencing academic difficulties, children and adolescents with anxiety disorders experience poor peer relationships. Because of cognitive distortions or maladaptive thinking patterns, these children and adolescents view their relationships with others more negatively. These negative perceptions of their relationships with others reduce the likelihood of interactions with peers. These individuals may feel socially isolated and experience depression and feelings of hopelessness.

Symptoms of anxiety can significantly interfere with children or adolescents' social-emotional and academic functioning. In light of these concerns, children and adolescents with an anxiety disorder may be eligible for special education and related services under the Individuals with Disabilities Education Improvement Act of 2004 (IDEA). Specifically, anxiety disorders are categorized under the emotional disturbance (ED) category of disabilities. To meet the criteria for an emotional disturbance, a student must exhibit one or more of the following conditions, and the condition(s) must have occurred over a long period of time and to a marked degree and must adversely affect the individual's educational performance:

1. An inability to learn that cannot be explained by intellectual, sensory, or health factors

2. An inability to build or maintain satisfactory interpersonal relationships with peers and teachers

3. Inappropriate types of behavior or feelings under normal circumstances

4. A general pervasive mood of unhappiness or depression

5. A tendency to develop physical symptoms or fears associated with personal or school problems (34 C.F.R. § 300.8)

Assessment of Individuals With an Anxiety Disorder

To detect an anxiety disorder or high levels of anxiety in individuals of different ages, a multimethod approach

to the assessment of anxiety is recommended. A multi-method approach involves the use of different types of measures completed by multiple informants across multiple settings to detect anxiety and comorbid conditions. A variety of assessment techniques, including clinical interviews, rating scales, direct observations, self-report, and psychophysiological measures, are available to assess anxiety in individuals of different ages. Many of these measures are completed by multiple informants (self, parent, spouse, and/or teacher) across multiple settings (home, school, and/or work).

Treatment of Anxiety

Once an assessment or evaluation is completed and high levels of anxiety are detected or an anxiety disorder is diagnosed, assessment results are linked to interventions to ameliorate anxiety and its negative effects. Different treatment strategies are available to address anxiety, including pharmacotherapy, behavioral strategies, and cognitive-behavioral interventions. Additional strategies may also be used to address comorbid issues. Thus, a multimodal approach, consisting of two or more interventions, is often used to alleviate an individual's anxiety and its negative effects.

Pharmacological treatment is one means of alleviating anxiety in individuals. Medications that have been used to treat anxiety include benzodiazepines, selective serotonin reuptake inhibitors, tricyclic antidepressants, and buspirone. Medication is often used in combination with other treatments such as cognitive-behavior therapy because although the medication may reduce anxiety symptoms, it does not help individuals learn to cope effectively with their anxiety.

Behavioral interventions are another means of reducing anxiety in individuals. Relaxation training, systematic desensitization (graduated exposure), and modeling are some of the behavioral strategies used to treat anxiety. These strategies have been shown to be effective. Relaxation training may include deep breathing exercises or progressive muscle relaxation. Progressive muscle relaxation involves individuals learning to relax and tense different muscle groups in order to become more relaxed. Relaxation training may also be found in systematic desensitization. In systematic desensitization, a fear hierarchy is created, consisting typically of 10 to 15 steps evenly spaced. For example, if an individual had a fear of large dogs, the first step in the fear hierarchy may consist of a discussion about dogs. The second step may involve

looking at a picture of dogs. The third step of the fear hierarchy may involve driving past a pet shop and so on until the last step, when the individual pets a real-life dog. The purpose of creating a fear hierarchy is to gradually expose the individual, step by step, to the feared stimulus. The graduated exposure can be conducted using imagery or real-life experiences. Relaxation or another incompatible response to anxiety is induced along the way to calm the individual as graduated exposure of the feared stimulus occurs. Modeling is another behavioral strategy used to reduce fears and anxieties. Modeling is based on social learning theory in which an individual observes, either live or on film, a person who interacts successfully with the feared stimulus or situation. The model is typically of the same age and gender as the individual. After watching the model interact successfully with the feared stimulus or situation, the individual is more likely to perform the same behavior, and the fear and anxiety associated with the feared stimulus or situation are reduced.

Cognitive-behavioral strategies, such as self-instruction, self-control training, and rational-emotive therapy, have also been used to alleviate individuals' anxieties. Self-instruction involves the use of positive self-talk to handle anxiety-provoking situations. In self-control training, individuals learn to modify and restructure maladaptive thoughts, resulting in less anxiety in the presence of anxiety-provoking stimuli or situations. Less anxiety experienced then leads to positive changes in behavior because these individuals are more likely to approach the feared stimuli or situations. Replacement of false, irrational beliefs that underlie an anxiety problem with rational beliefs is the focus of rational-emotive therapy.

Prevention of Anxiety

Because anxiety is a common mental health concern facing many Americans today, efforts should be directed toward the prevention of anxiety disorders. The emotional, social, and economic costs associated with anxiety disorders are astronomical. Economic costs alone are estimated to be more than $40 billion per year. Yet, few prevention programs exist. Although prevention programs are costly up front, universal (primary), selective (secondary), and indicated (advanced) prevention programs are needed. Future efforts should be directed toward the development and implementation of these programs, as there will never be enough

mental health professionals to provide adequate treatment of anxiety and other disorders.

Applied Behavior Analysis

Applied behavior analysis is a methodology for systematically applying the principles of learning theory to develop interventions that will improve socially significant behaviors to a meaningful degree, as well as demonstrate that the interventions employed are responsible for the improvement in behavior. Applied behavior analysis has been repeatedly demonstrated to be a highly effective approach across a wide range of problems and environments, including education, mental health and mental retardation, parent training, environmental management, and organizational management. Applied behavior analysis is a specialty used by various professions. It is not regulated by most states, except as part of psychology or other established professions, although there have been a few attempts to recognize trained and qualified behavior analysts over the years. Most recently the nonprofit Behavior Analyst Certification Board has promoted a national certification program to identify and credential qualified practitioners and trainers.

Principles and Techniques

Several terms besides *applied behavior analysis* have been used to describe intervention methods based on behavioral learning theories, including *behavior modification, behavior therapy*, and others. Although sometimes used interchangeably, there are possible distinctions made. Applied behavior analysis is used

most often for the orientation that derives predominantly from Skinnerian operant conditioning and follows a radical behavioral philosophy. Although other behavioral orientations often utilize operant principles to differing degrees, they typically place a greater emphasis on classical conditioning processes (the neo-behavioristic mediational model) or cognitions and perceptions as targets for change (social learning theory and cognitive behavior modification) than does applied behavior analysis.

Operant conditioning eschews hypothetical mental constructs as explanatory contracts. Behaviors are viewed as being selected by environmental consequences, much like adaptive changes are in Darwinian evolution, rather than being emitted to serve some future purpose. That is, a child does not cry in order to attract attention but cries because crying has resulted in reinforcing consequences in similar situations in the past (unless, of course, the crying is in response to actual physical discomfort).

The central precept of applied behavior analysis is that behaviors are under the control of environmental stimuli. Functional relationships are described by a three-term contingency that consists of antecedents, responses (behaviors), and consequences. At times these are referred to as the ABCs of behavior. Early uses of behavior analysis focused primarily on changing behaviors through manipulating consequences. All consequences are seen as directly influencing whether behaviors will recur in the future. Consequences can be grouped into three main types: reinforcing, punishing, or neutral stimuli.

The first class of consequences, *reinforcers*, consists of events that increase the future probability of a behavior they immediately follow. These include events that strengthen behaviors when they are presented following the behavior, such as food, attention, or social praise. This operation is referred to as *positive reinforcement*. For example, a child may learn to apologize because the apology consistently is followed by parental praise. Behaviors also can be strengthened through the removal of an aversive (negative) stimulus following a behavior. This operation is termed *negative reinforcement*. This would be the case if a child learns to apologize if the apology terminates (or avoids) being scolded by his or her parents.

Reinforcers can either be biologically preestablished (*primary reinforcers*), such as food or water, or can acquire reinforcing properties through careful pairing with primary reinforcers (*conditioned reinforcers*).

Most reinforcers are differentially effective with different people rather than being universal. This is particularly true of conditioned reinforcers such as praise or tokens. The *schedule of reinforcement* used to deliver reinforcers also is important. Early in the process of strengthening a behavior, reinforcers are typically delivered on a continuous schedule, where a reinforcer is given each time the response occurs. Later in the process, various schedules are used that deliver reinforcers more intermittently and help increase resistance to extinction and/or produce specific types of responding patterns.

Punishment consists of two operations, but these weaken the likelihood of behaviors recurring. In *positive punishment*, the presentation of the consequence following the behavior results in weakening future occurrences of a behavior. An example might be a brief swat on the bottom when a young child chases a ball into the street. Removing a reinforcing stimulus contingent upon a behavior also can weaken it. This is *negative punishment* and includes, for example, taking away television-watching privileges for a short time to weaken a child's lying behavior. Applied behavior analysts typically advocate negative punishment as a more appropriate reductive method in most cases.

Behavior also may be decreased through the use of *extinction*, where the connection between a response and its maintaining consequences is discontinued, leading to a progressive decline in the rate of a previously reinforced response.

Antecedents, which are the front end of the three-term contingency, influence behaviors largely through a prior history of differential association with reinforcing or punishing consequences. When a child's behavior has been reinforced previously in a situation, the likelihood of that behavior is heightened under similar circumstances. It is lowered in situations in which reinforcement has been consistently withheld or punished. For example, a child whose father consistently buys him candy in a store when he whines is likely to exhibit similar behaviors in the future when shopping with his father. With his mother, who does not "give in," the child will learn not to whine.

Another type of antecedent stimulus used programmatically includes visual, verbal, or physical *prompts* given to increase the likelihood a child will respond appropriately to the given situation. For example, pictures of objects may be placed with letters to assist a child in learning letter sounds. These can then be

removed either abruptly or through a gradual process called *fading. Modeling* can be seen as a special form of prompting in which someone demonstrates a desired behavior to increase its likelihood.

When a behavior is not present in the individual's repertoire, the procedure of *shaping* or *successive approximations* may be used. Shaping involves reinforcing progressively closer approximations of the desired behavior. For example, in teaching new words to a young child, the child is reinforced for vocalizations that are increasingly more like the desired word. As the sequence progresses, the word must be more and more like the target word for the child to receive reinforcement.

Particularly important behavioral concepts for instructional applications include *discrimination*, *generalization*, and *concept formation*. Behaviorally, concept formation occurs when the same response occurs to a group of discriminably different objects that have some aspect in common (as well as responding differently to other classes of stimuli). Concept formation involves both generalization and discrimination: generalization within classes and discrimination between classes. Thus, a child who responds "dog" to different examples of dog but not cats or other animals is exhibiting concept formation.

Many other effective techniques have evolved over time from this relatively small set of basic principles. In addition to those just mentioned, these include procedures such as *overcorrection*, *token economies*, *time-out*, *response cost*, *self-monitoring*, and *task analysis*.

Methodological Practices

Although numerous step-by-step models have been proposed for developing, implementing, and evaluating applied behavior analytic interventions, each generally incorporates at least the following components:

1. Selecting a behavioral excess or deficit for change

2. Establishing a method for measuring behaviors

3. Measuring the baseline (current) level of performance

4. Specifying goals and objectives

5. Designing and implementing interventions to teach or strengthen behaviors/skills and/or to reduce excessive behaviors

6. Continuously measuring the behaviors to determine the effects of the intervention

7. Modifying the intervention based on ongoing measurements

In measuring behavior, applied behavior analysts focus on observable behaviors recorded using techniques such as direct observational recording (event, duration, or latency recording using continuous, time sampling or interval recording) and analysis of permanent products. In recent years, the practice of *functional behavioral assessment*—where the functions or maintaining factors of an existing behavior are determined experimentally prior to designing an intervention for implementation—has become increasingly more important.

A particularly important aspect of applied behavior analysis is the demonstration that the intervention used, rather than some unspecified extraneous variable, caused the behavior change. Applied behavior analysts accomplish this primarily through within-subject experimental designs that focus on the functional relationships between intervention changes and changes in target behavior. Typical experimental designs include reversal (ABAB) designs, multiple baseline designs, multiple-treatment designs, and changing criterion designs. The generality of effects is established through replication across subjects over time.

Historical and Current Applications

The field of operant conditioning, or the experimental analysis of behavior, began to grow exponentially during the 1930s. At that time B. F. Skinner built upon the basic concepts of radical behaviorism espoused by John Watson. Within a few years early attempts were made to apply Skinner's model of operant conditioning to human behavior and development. This was accompanied by a number of research programs, mostly in institutional settings. That work used arbitrary responses, as in animal operant research, to investigate the applicability of operant conditioning to humans. Concurrent with this, a few psychologists began working with the mentally retarded and mentally ill in clinical settings. The often-cited first human application, published in 1949, demonstrated that squirts of milk could be used to establish arm raising in a profoundly retarded 18-year-old man. Examples of other early applications included use of psychiatric nurses to change behaviors in psychotic patients and early attempts to change problem behaviors in preschool children.

During the late 1960s the field became increasingly focused on the application of operant principles to socially important problems rather than artificial laboratory research. The *Journal of Applied Behavior Analysis* was founded in 1968 as a primary outlet for this research. In the initial volume, Donald Baer, Montrose Wolf, and Todd Risley proposed seven defining dimensions of applied behavior analysis. When the same authors reviewed the status of these dimensions almost 20 years later, they concluded that the dimensions continued to be relevant. First, the behaviors or stimuli studied must be selected for applied (practical) rather than theoretical significance. They must need improvement and be measurable (behavioral). It is essential that the factors responsible for the occurrence or nonoccurrence of the behavior be established (analytic). The behavior change procedure used needs to be described in terms of the relevant principles (conceptual systems) and must be completely identified and described to permit replication of the interventions (technological). Behavioral techniques used must produce significant practical effects (effective). Lastly, those effects must be stable over time and situations, or they must extend to untrained responses (generality).

Since the 1950s applied behavior analysis has become an increasingly important applied field of psychology that has been used to modify behaviors across numerous areas of human functioning, including mental health and mental retardation, general and special education, organizational performance management, environmental management, and behavioral medicine.

Applied behavior analysis has been extended across many areas of education over the past few decades. Besides the obvious clinical applications for individuals with disabilities, a number of instructional methods used across regular education, special education, or adult and higher education have been grounded in applied behavior analytic principles. These include *direct instruction*, *precision teaching*, and *personalized instruction*. Although there have been numerous studies demonstrating the effectiveness of these approaches, they have not been widely adopted. In fact, numerous appeals have been made to have education be more accepting of applied behavior analysis as a basis for instructional innovations.

APTITUDE

Aptitude can be defined as individual differences that are related to subsequent learning during a fixed time frame. The learning or acquisition of knowledge or skills can occur in a formal intervention (training or education) or in an informal setting (experience or mentoring). This definition can be fruitfully narrowed by specifying the domain of individual differences (cognitive, noncognitive) and the type of relationship (i.e., rate, accuracy) with learning. Numerous individual differences are related to learning, including cognitive abilities, personality traits, interests, and values. All of these can be considered aptitudes, and all can be evaluated in work, school, or avocational contexts. Aptitudes are discussed most commonly in reference to cognitive abilities within a formal educational or training context where the learning is labeled achievement.

However, this general definition defines aptitude mainly by its relationships with learning outcomes. If one also considers the nature of an aptitude, one finds two fundamentally different underlying definitions of aptitude. The failure to differentiate between these two conceptualizations can be the source of much confusion. The first definition proposes that aptitude comprises individual differences that develop from a combination of innate and environmental influences. Aptitude reflects a current repertoire of behaviors and behavioral tendencies that predict subsequent learning.

The second and quite different definition proposes that aptitude comprises individual differences that are innate and largely unchanging and immutable within normal circumstances. That is, aptitude is raw material that either facilitates learning or is actively used to learn. In the first definition one might say that a field had a strong aptitude for growing crops even though this is partially a function of having been covered with artificial fertilizer. The second definition would characterize the aptitude of the field based only on the fundamental and natural composition of the soil. The expected patterns of empirical findings that would be consistent with each definition differ.

The first definition frames aptitude as a reflection of current capabilities and tendencies. An aptitude is current skill and knowledge. In this case aptitude is based on a person's innate potential as it has been developed through learning opportunities and environmental stimulation or deprivation. Under this definition, aptitude is not a clear window into innate talent and will predict future learning but may also change itself due to new learning experiences. This means that aptitude scores may show mean increases, variance changes, and rank order changes after learning has occurred. For example, an algebra exam is likely to predict learning of trigonometry. Algebra scores at Time 1 will correlate with trigonometry scores at Time 2. Trigonometry scores are also likely to increase from Time 1 to Time 2. Finally, if some students are fundamentally more innately skilled at math but have not previously had the opportunity to receive good training or engage in deliberate practice, nonchance rank order changes, and a decrease in the variance on the measure of algebra knowledge and skill between Times 1 and 2 may also be observed. The argument that the algebra test is an aptitude for learning trigonometry would be strengthened if it predicts Time 2 trigonometry scores above and beyond what trigonometry knowledge at Time 1 predicts.

In the second definition one would expect that aptitude would remain unchanged by subsequent experiences, intervention, and learning. One researcher, Carroll, proposed that the ideal case for specifying an aptitude could be framed with six conditions. At Time 1 there would be (1) meaningful differences on the aptitude measure but (2) no valid variance on the achievement measure. Condition 2 also results in the implicit but unstated condition that achievement at Time 1 is uncorrelated with achievement at Time 2. (3) The aptitude measure would not be correlated with the achievement measure at Time 1 (prelearning event), and (4) the means and rank order of people on the aptitude measure would not change from Time 1 to Time 2. (5) However, the achievement measure would increase from Time 1 to Time 2, and (6) scores at Time 2 would become correlated with the aptitude measure. In other words, one would see an increase on the achievement measure from no knowledge to differences in knowledge among people, and the unchanging aptitude measure would predict these increases and differences. A few situations generally fit these conditions. Two clear examples are musical training and learning a foreign language, where students have not typically been exposed to the instrument or language and the predictors of learning are not strongly influenced by the educational training. However, in most cases, the achievement domain is based on, or connected to, an area of previous learning (e.g., calculus after having studied algebra or graduate-level psychology after having studied introductory psychology). In addition, aptitude is not unchanging and static. Aptitude, achievement, and ability are difficult to cleanly distinguish from one another.

Aptitude, Achievement, and Ability

Cognitive aptitude tests are commonly contrasted with achievement or ability tests. In nearly all cases, the distinction among the three is more semantic than substantive. Although cognitive tests can measure a very wide range of different abilities, they still measure acquired knowledge and skill; they all assess ability. A person's ability is the extent to which that person is able to correctly do the tasks directed toward a goal. Ability is simply a person's current capabilities. Therefore, aptitude is the potential to attain ability, and achievement is an improvement in ability. Current ability and aptitude levels are a function of prior achievements. Scores reflect gains in learning from some point in time. Finally, prior learning is consistently a good predictor of subsequent learning, and so the tests also evaluate aptitude. Therefore, the distinction among ability, achievement, and aptitude is often artificial.

A more productive taxonomy begins by considering four dimensions: the breadth of material sampled, curriculum represented, recency of learning sampled, and purpose of the assessment. A measure with a broad sampling would measure behaviors from a number of different domains. Tests with multiple different subtests, like the Wechsler Adult Intelligence Scale (WAIS), are

a good example of broad breadth. Curriculum represented is the extent to which a measure is linked to specific training or educational programs instead of more general or informal learning. The extent to which the curriculum represented in the measure reflects the experiences of the people being evaluated is sample dependent. Recency of learning refers to whether the measure captures more historical learning versus recently taught material. The recency of learning is dependent on the age and background of the sample being assessed. The purpose refers to the applied use of the measure, for example, prediction, assessment, training evaluation, placement, or counseling.

The combination of high breadth, a lack of formal curriculum representation, historical learning, and the purpose of evaluating current capacities would characterize an ability measure. In contrast, an assessment with low breadth, for example, a specific course or educational year's curriculum that was recently taught for the purpose of measuring student learning during the course, would typify an achievement measure. An aptitude measure might take the form of modest breadth and relatively recent learning in a specific curriculum to be paired with the purpose of assessing potential for the same domain. Alternatively, if one is uncertain about the specific nature of the learning domain (e.g., college major is not fixed) or wishes to assess potential for a broad array of domains (e.g., a liberal arts education), one might measure aptitude with high breadth, for example, a general or core curriculum from relatively recent learning experiences.

The taxonomy of four different characteristics of a cognitive measure illustrates the ever-present bandwidth fidelity trade-off. In a given period of time there is always a trade-off between the breadth and precision of measurement. Take, for example, an introductory psychology course. Using a 2-hour final exam, the instructor can either do a very broad but low fidelity assessment of a student's learning in the course or gain more precision about a narrower aspect of introductory psychology. The decision about what to evaluate and in what detail should be based on the goals of the assessment.

Correlations Between Aptitude and Criteria

Both cognitive and noncognitive aptitude measures have been shown to be predictive of learning and other accomplishments. Cognitive and noncognitive measures predict, to a moderate degree, subsequent acquisition of knowledge and skill in laboratory studies. These relationships hold for tasks that range from simple learning and memory to complex cognitive skills. In the educational domain, aptitude tests predict educational outcomes both early and later in school. A large literature has demonstrated the relationship between aptitude measures and performance in higher education. In the work domain, aptitude measures are associated with success in organizational training programs.

Nature and Nurture in Aptitudes

Research that has attempted to model the development of knowledge and skill suggests that personality traits, interests, and cognitive abilities are associated with the amount and domains of learning a person acquires. A person's ability and preferences appear to influence the direction of the educational and work careers as well as the types of things the person achieves. Both cognitive and noncognitive types of aptitude have a widespread influence on people's lives, and research indicates that biology plays a role. Research on aptitude measures has demonstrated that, as currently assessed, these individual differences have strong heritable and environmental components. Differences across people appear to be due to a combination of genetic and environmental factors. This also appears to be true for personality traits. People are predisposed to have certain behavioral tendencies, but the expression of these tendencies is also strongly influenced by the environment. New research has begun to identify brain structures that are associated with cognitive aptitudes. Specifically, the lateral prefrontal cortex appears to be implicated in general cognitive ability. However, this research takes us full circle to the two initial definitions of aptitude. Despite clear biological links with aptitude, this research does not demonstrate that differences among individuals, groups, or genders are necessarily due to an innate source.

APTITUDE TESTS

Aptitude can be defined as any characteristic that affects an individual's response to instruction or treatment. An *aptitude test* is intended to measure characteristics that influence the likely or potential response to environmental stimuli. Test outcomes are often used to predict future performance. Common characteristics associated with aptitude tests include intelligence, career skill/interest, and personality. Aptitude is typically identified as a characteristic of an individual. However, success is defined by both the characteristics of the individual and the ecology in which the individual exists. The aptitude for high academic achievement cannot be realized without the necessary experiences to promote learning and achievement.

Aptitude can be conceptualized as readiness to thrive. The outcomes from college aptitude tests, such as the Scholastic Aptitude Test, are used to guide admission decisions. They provide information about the student's capacity to thrive and learn academic material presented in higher education. The outcomes from career-related aptitude tests, such as the Strong Interest Inventory, provide information about individual characteristics that influence potential responses to job training.

The first aptitude tests were developed by Sir Francis Galton in the late 19th century to measure intelligence. The approach was later popularized by Alfred Binet and his colleagues when they developed and introduced the Binet Intelligence test. The Binet was used in France to identify those students who were most likely to benefit from public education. The underlying assumption associated with the use of the Binet was that there were individual differences that affect the potential to learn, and public financing should be spent to educate the students with the most potential. The assumption of individual differences endures today; however, intelligence tests have gone through much refinement through the years. In addition,

the success of such tests spawned various types of aptitude tests to address the diverse measurement needs of practitioners.

Aptitude tests vary in the number and specificity of the characteristics measured. Some measure broad aptitudes, such as general intelligence, scholastic ability, or personality; others target narrow aptitudes, such as mathematical or mechanical abilities. These tests are widely used in schools, counseling centers, and clinics as one piece of information within a comprehensive assessment. There are several categories of aptitude tests, and the following sections provide background information on development of aptitude tests and practical information on various types of aptitude tests, including intelligence tests, scholastic achievement tests, personality tests, and career tests. Finally, historical and present uses of aptitude tests are discussed

Intelligence Tests

As briefly mentioned in the previous section, testing of mental capacities began in the late 19th century by Sir Francis Galton. The foundation of his intelligence theory was the knowledge that people interacted with the environment through the five senses. This led Galton to theorize that the most intelligent people had innate abilities for enhanced sensory discrimination and retention of information. Galton opened a laboratory and collected a large amount of information at public gatherings, including the World's Fair. He made his measures available to the public; however, the tests proved to be problematic. The first practical intelligence test was developed and disseminated around 1905 by Alfred Binet and his colleagues in France. The Binet–Simon Scale was commissioned by the French government to screen children for mental retardation. It was the first test to consider cognitive development in children, rank items by level of difficulty, and use a standard form of instructions throughout the test. The test was brought to the United States in 1908 by Henry H. Goddard and then adapted in 1916 by Lewis Terman at Stanford University. It is in this revision that the test was renamed the Stanford–Binet, and it remains one of the most popular intelligence tests given in schools.

After the introduction of intelligence tests to the United States, the Army created the first group-administered intelligence test. This test was dubbed the Army Alpha and comprised a series of questions

with true-or-false responses that covered content which included vocabulary, arithmetic, sentence structure, general knowledge, and practical judgment. The test was given to incoming soldiers during the final years of World War I in order to place soldiers in officer or infantry tracks. The Army also developed a nonverbal version of the test, the Army Beta, to provide the testing opportunity for those who did not speak or write in English and minimize misclassification of the non-English-speaking soldiers as less intelligent and therefore only appropriate for infantry service. This large-scale testing endeavor resulted in other large-scale testing programs and evolved into the Army's present-day testing program, the Armed Services Vocational Aptitude Battery.

Many other intelligence tests followed the Stanford–Binet and Army tests. One of the most popular is the Wechsler intelligence tests, which is a series of four intelligence tests for use with children and adults. The series includes a preschool version, child version, adult version, and a brief version for use with individuals across the testing age span. David Wechsler developed the first version, the Wechsler–Bellevue Intelligence Scale, in 1939 by combining subtests from various other intelligence tests, including the Stanford–Binet, Army Alpha, Army Beta, and Kohs Block Design Test. The most recent version geared toward children, the Wechsler Intelligence Scale for Children–IV (WISC–IV) was released in 2003, and the Wechsler Adult Intelligence Scale (WAIS, 1997) is in its third revision.

A more recent addition to the intelligence testing community is the Woodcock-Johnson–III Tests of Cognitive Abilities (WJ–III Cog, 2001). The WJ–III Cog development is theoretically based on the Cattell-Horn-Carroll theory of intelligence (CHC theory), which is the most widely accepted theory of intelligence within the field of psychology. The original Woodcock-Johnson Psycho-Educational Battery was published in 1977 and was the first co-normed battery of cognitive abilities, scholastic achievement, and interests for individuals of a wide age range. The first revision in 1989 separated the larger test into two distinct batteries, Tests of Cognitive Abilities and Tests of Achievement. The two test batteries share a large normative sample, which provides greater validity when making comparisons between the two tests within individuals, such as analysis of intelligence and achievement discrepancies for special education eligibility decisions.

Academic Achievement Tests

Intelligence tests are often accompanied by tests of academic achievement that provide a measurement of specific academic skills in content areas such as reading and math. The purpose of achievement tests is to measure individual academic strengths and difficulties. Outcomes can be used to describe and predict performance within the academic context. There are comprehensive achievement tests that cover a variety of academic skills (i.e., reading, math, social studies, science), and there are achievement tests that aim to measure a single academic skill (narrow-band tests) in more detail than is possible with a comprehensive test.

Achievement tests are administered in many contexts that include both group and individual administration. Group-administered tests include state accountability tests, such as the Iowa Tests of Basic Skills and college entrance exams (e.g., Scholastic Aptitude Test [SAT], Graduate Record Exam [GRE], and American College Testing [ACT] program). Individually administered tests are generally used within the context of special education eligibility assessments and include the Woodcock-Johnson–III Test of Achievement, Stanford Achievement Test, Wechsler Individual Achievement Test, and many narrow-band assessments (e.g., Gray Oral Reading Test–IV).

Individually administered achievement tests and state accountability tests are not often considered aptitude tests because the purpose of the test is quite different from the defined application of aptitude tests. Individual achievement tests are used to describe student strengths and difficulties at the time the test is given. These data are then used to make decisions about the provision of supplemental academic services, such as classroom interventions or special education, but the data are not used to predict future scholastic attainment. The data from state accountability testing are also used for the purpose of description of current academic achievement but are not often used to predict student achievement in the future.

College aptitude tests represent one of the largest and best-known applications. They are used to guide admissions to colleges and universities at both undergraduate and graduate levels. Students begin to prepare for college entrance exams as early as middle school, but more frequently the preparation begins in the sophomore year of high school. The Preliminary Scholastic Aptitude Test (PSAT) is a preparatory test, similar in format to the SAT, which provides students

with the opportunity to practice taking a college entrance exam without the pressure of sending scores to colleges and universities and also acts as an assessment for the National Merit Scholarship competition. Scores on the PSAT can be used to predict future performance on the SAT and as the first step in the evaluation of students for the National Merit Scholarship.

The PSAT is followed the next year with the SAT and/or the ACT. Colleges and universities across the country use these academic achievement scores as part of the admission criteria. The SAT was developed by the Educational Testing Service of Princeton at the request of the College Board and is one test in a series of large-scale assessments that also includes the PSAT, the high school Advanced Placement tests, and the Graduate Record Examination (GRE). The SAT general test consists of three subtests that measure critical reading, mathematics, and writing. Subject tests are also available and fall within five major subject areas: English, history, science, mathematics, and languages. Colleges do not often require subject tests but encourage students to take one or more of the subject tests for proper placement within tracked courses, such as mathematics.

The ACT is the largest competitor of the SAT. It was developed in 1959 by E. F. Lindquist with the University of Iowa Testing Programs. The test was developed to assess the academic skills needed to succeed at the college level and measures content that is regularly taught in high school curricula. The test comprises five subtests that assess reasoning and problem solving in English, mathematics, reading, and science. The writing portion of the test is optional. Similar to the SAT, the ACT provides academic achievement scores, but it differs from the SAT with the addition of career interest items given in combination with the academic content. The final score report provides information about academic and career interests of the individual for college and career planning purposes.

Similar to the undergraduate college admission process, graduate programs also require aptitude testing. Graduate programs require the GRE General Test and often recommend GRE Subject Tests as a measure of achievement in a specific area of undergraduate study. The GRE General Test measures skills in verbal and mathematics reasoning, critical thinking, and analytical writing that are acquired throughout the many years of education and are not specific to any field of study. The GRE Subject Tests are available for eight specialty topics: biochemistry, cell and molecular biology,

biology, chemistry, computer science, literature in English, mathematics, physics, and psychology. Professional schools (i.e., medical school and law school) do not require the GRE but instead require tests that measure aptitudes required by the profession. The Law School Admission Test (LSAT) is administered by the Law School Admission Council and is a test of logical and analytical reasoning, reading comprehension, and analytical writing skills. Scores on the LSAT are used as a criterion in law school admissions decisions because they positively correlate with first-year law school grades. The Association of American Medical Colleges developed the Medical College Admissions Test (MCAT). The MCAT measures verbal and writing skills and knowledge in biological and physical sciences and is an admissions requirement at almost all medical schools in the United States.

Career Tests

Aptitude tests are not limited to scholastic abilities and skills. Whereas some individuals may understand their personal skills and interests well enough to choose a career easily, others many have trouble with this process and need guidance. Career aptitude tests were developed to help guide individuals in the process of career decision making.

The Differential Aptitude Test and General Aptitude Test Battery were both designed to assess various cognitive and physical abilities and provide guidance to individuals making vocational decisions. They are designed to reflect differences among the various aptitudes, which include verbal and numerical reasoning, mechanical and clerical aptitudes, manual dexterity, and motor coordination. The interpretation of scores on these tests is directly related to various occupations. Individuals are provided with lists of career and vocational environments that best match the pattern of aptitudes reflected in their test scores.

Another type of career-related aptitude test is the interest inventory. The Strong Interest Inventory was developed in the 1920s by E. K. Strong and is based on John L. Holland's vocational choice theory. Holland theorized that people and work environments could be categorized into six basic types: Realistic, Artistic, Social, Investigative, Enterprising, and Conventional. Holland believed that people are most happy in their work when personality, skills, and interests match the work environment. Very few individuals and work environments can be categorized as a pure

type; therefore, Holland theorized that each could be categorized as a combination of three of the six basic types. With Holland types as a foundation, the Strong Interest Inventory was developed through discussions with individuals who were happy with their work environments, and the 219 items subsequently created ask clients to rate their interests in careers, skills, and job-related tasks. The reported scores on this test are quite different from those received from intelligence and achievement tests because there are no incorrect answers on this test. The client receives a three-letter type code that corresponds to Holland's six basic types and is related to the careers of those who were interviewed in the development of the test. The report also provides a list of careers the individual might enjoy and, in the case of high school or college students, a list of college majors the individual might consider.

While the Strong Interest Inventory is quite popular, the Myers-Briggs Type Indicator (MBTI) is one of the most popular of all career-related aptitude tests. It is often used in the context of career guidance, but it was developed as a test of personality types. The MBTI was developed by Katharine Cook Briggs and Isabel Briggs Myers in the mid-20th century and is based on the personality theories of Carl Jung. The MBTI is composed of 93 forced-choice items whose responses are then sorted into four types. The four bipolar scale types, known as dichotomies, are introversion/extroversion, sensing/intuition, thinking/feeling, and judging/perceiving. The test results in a four-letter code that refers to the preferences of the individual on each of the four dichotomies. For example, a person might receive a code of ESTJ, which places that person on the extroverted side of the continuum, sensing is considered stronger than intuiting, thinking is stronger than feeling, and the individual is more of a judger than a perceiver.

The Strong Interest Inventory and MBTI are often used in conjunction as a battery for career guidance assessment. Whereas the Strong Interest Inventory has a strong support for reliability and validity in the research literature, the MBTI has much less support and should not be used for decision-making purposes but rather for personality and career exploration in conjunction with other career aptitude measures.

Personality Tests

Large-scale intelligence testing began during World War I with the need for U.S. Army personnel to

properly place new soldiers into positions that best suited their interests and skills. The need for placement of World War I soldiers also influenced the development of personality tests. Robert Woodworth developed a series of forced-choice items that were used to screen soldiers for potential mental health problems such as excessive anxiety. Others followed with their contributions to personality assessment, but personality inventories were not widely used in the general population until Robert G. Bemeuter developed his Personality Inventory in 1930. Personality assessment became even more widespread with the introduction of the Minnesota Multiphasic Personality Inventory (MMPI), a personality inventory that measures emotional and social disturbance. The MMPI was developed by Starke Hathaway and J. C. McKinley in 1943 to aid in diagnosis of psychiatric patients and is the mostly widely researched instrument in print. The MMPI was developed empirically by asking patients diagnosed with a wide range of psychiatric disorders and a large number of control participants to respond to a series of true/false statements. They identified 504 items that differentiated between the 221 clinical patients and the pool of 1,508 control participants. The MMPI was revised in 1989 with updated items and a more representative normative sample. The MMPI–2 contains 567 items, 10 clinical scales, 3 validity scales, several content and supplementary scales, and a list of critical items all developed by various researchers. The 10 clinical scales are Hypochondriasis (Hs, 1), Depression (D, 2), Conversion Hysteria (Hy, 3), Psychopathic Deviant (Pd, 4), Masculine-Feminine Interest (MF, 5), Paranoia (Pa, 6), Psychasthenia (Pt, 7), Schizophrenia (Sz, 8), Hypomania (Ma, 9), and Social Introversion (Si, 0). The clinical scales retained the original names even though many of these terms are not used in present-day psychology. Today the scales are commonly referred to by number. Recently, the Restructured Clinical scales were developed by Auke Tellgen to aid interpretation and provide greater alignment with the present categorical system used in psychology diagnosis. The MMPI–2 can only be used with adults 17 years of age or older. There is an adolescent version, the MMPI–A, but a version for childhood assessment is not available.

In contrast to the MMPI–2, which aims to measure disordered personality tendencies, other personality tests aim to measure normal personality traits. The NEO-Personality Inventory (NEO-PI) was developed

to measure the Five-Factor Model of personality. The five factors are Neuroticism, Extroversion, Openness, Conscientiousness, and Agreeableness. The Five-Factor model of personality is one of the most widely accepted trait theories of personality. Whereas the MMPI was empirically derived, the NEO-PI is based on theory, and items were chosen through the employ of elaborate statistical procedures. The NEO-PI is often used in employment settings, but there is some research to support its use in clinical diagnosis. Similar to the MMPI, the NEO-PI was standardized for use with adults only.

Children's personality inventories are also available and include the Child Behavior Checklist, the Children's Depression Inventory, and the Behavioral Assessment System for Children (BASC). However, these inventories are not referred to as personality tests because it is widely understood personality is not stable until early adulthood; therefore, temperament and behavior are measured prior to adolescence. Childhood assessments commonly include items for parents, the child's teacher, and self-report from the child. This multisource approach provides greater reliability and validity of the assessment. The BASC–2 (revised in 2006), developed by Cecil R. Reynolds and Randy Kamphaus, is a widely used assessment that combines parent, teacher, and student self-reports along with a direct behavioral observation system. This multisource, multimethod comprehensive assessment is used frequently in educational and clinical settings for the purpose of behavioral and mental health assessment of children.

There are a large number of personality inventories available for use with clinical, educational, and normal populations, but a description of each is outside the scope of this entry.

Application of Aptitude Tests

Whereas this entry takes a broader view of aptitude as put forth by Robert Snow, aptitude is often considered synonymous with intelligence. Throughout the mid-20th century, when psychological and educational research began to flourish, there was an increased interest in using intelligence tests to pinpoint cognitive difficulties and subsequently provide interventions to individuals based on the intelligence scores. Interventions targeted specific difficulties as indicated by the intelligence test. This process is referred to as an *aptitude by treatment interaction*

(ATI) approach. ATI was often used as a mechanism to diagnose and treat learning disabilities, but decades of research have concluded that ATI did not function to increase student cognitive skills, especially the academic skills valued in education, such as reading and mathematics.

Currently, the accepted use of aptitude tests is as part of a multisource, multimethod assessment where the aptitude test provides only one piece of the information used in the determination of intervention for an academic or behavioral difficulty. Aptitude tests function to predict future performance, and the addition of information from various sources (i.e., parent, teacher) and different assessment methods (i.e., behavioral observations, record review) increases the accuracy of future performance.

Implications

Aptitude is any characteristic that affects an individual's response to intervention. Although *aptitude* is often considered as synonymous with *intelligence*, the definition presented here provides a much broader view of aptitude that can include characteristics such as academic skills, personality traits, and career interests. Therefore, aptitude tests measure individual characteristics that influence responses to environmental stimuli and function to predict future performance.

The formal development of aptitude tests began in the mid-1800s and has since become a prolific psychological science that allows clinicians to predict future performance with increased precision. Historically, the use of aptitude tests was limited to an ATI framework, but the research has supported a broader use of these tests within a multimethod assessment. Aptitude tests can provide clinicians with information about individual characteristics that support readiness for treatment, intervention, or instruction. However, individual aptitudes do not necessarily translate into life success or the establishment of skills. They must be molded by complementary experiences. Those experiences might be formal, such as schooling, job training, or counseling. Those experiences might also be informal, such as interactions with family, friends, and daily problem solving.

In this age of prolific psychological research, tests are updated and new tests are developed. It is most important, when choosing an aptitude test, to understand the reliability and validity evidence, the intended

purpose of the test, and the population for which the test was developed.

ASIAN AMERICANS

The term *Asian Americans* refers to Americans, and immigrants living in America, whose ancestral heritage is linked to several Asian regions of the world: East Asia, Southeast Asia, and South Asia. The region of East Asia comprises a variety of countries like China, Japan, South Korea, North Korea, Taiwan, Hong Kong, Macau, and Mongolia; Southeast Asia consists of Cambodia, Indonesia, Laos, Malaysia the Philippines, Singapore, Thailand, and Vietnam; and the region of South Asia includes Bangladesh, India, Myanmar, Nepal, and Pakistan. Although Pacific Islanders (Hawaiians, Guamanians, and Samoans) may also be considered as Asian Americans, typically they are listed separately; therefore, they are not discussed here even though many of the issues discussed in this entry are applicable to the Pacific Islanders.

The Asian American population is not a homogeneous group. Yet, the term *Asian American* is used to categorize these diverse ethnic groups together. Although Asian Americans may share certain commonalities, they are an extremely diverse group of people from different countries and with rich cultures that are vastly different from each other. A true understanding of Asian Americans begins with their country's history, sociopolitical history in America, cultural practices and beliefs, language, conditions surrounding immigration, experiences after arrival in the United States, socioeconomic background, family situation, ethnic identity and assimilation, and length of residence in the United States.

Educational psychology has been interested in Asian Americans because they are a leading ethnic group with a long immigration history in the United States. Research with Asian Americans has focused on issues such as educational achievement, how they learn and develop in similar and dissimilar ways compared with White European Americans, and their psychosocial adjustment to mainstream American culture and schools. In the following paragraphs, Asian Americans are discussed along with their immigration history, Asian American subgroups, and Asian American issues.

Immigration History

The first Asian immigrants arrived in the United States more than 150 years ago; however, most Asian Americans arrived in the United States recently, after the adoption of the Immigration and Nationality Act of 1965. Prior to 1965, immigration from Asia had been barred by the National Origins Quota Act of 1924. In general, the Asian immigrants who moved to the United States as beneficiaries of the Immigration and Nationality Act of 1965 are characterized as highly professional and educated individuals. They arrived in the United States as skilled professionals, entrepreneurs, students, and family members of already naturalized Asian Americans. They migrated to the United States to seek better economic, social, and educational conditions. In contrast, Asian refugees, primarily from Southeast Asia, migrated to the United States as a result of war and political persecution and, thus, tended to be less educated and more economically disadvantaged.

The number of Asian Americans has grown more than eightfold since 1970. The U.S. Census Bureau estimated that there were approximately 12 million Asian Americans in the United States in 2005. The large population growth was the result of increased immigration from China, India, Korea, the Philippines, and other Asian areas after 1965 and the entry of more than 1.5 million Southeast Asian refugees following the end of the Vietnam War. The Asian American population is estimated to grow to 20 million by the year 2020.

Because of historical immigration patterns, Asian Americans tend to be highly concentrated in a few geographic regions. Currently, more than half of the Asian Americans reside in Hawai'i, California, and other West Coast states. In addition, the Asian American population is heavily concentrated in the major metropolitan areas such as Los Angeles, New York, San Francisco, Washington, D.C., and Chicago, where many ethnic enclaves exist. However, the patterns of these geographic concentrations differ greatly from one Asian ethnic group to another. Furthermore, more recently, the Asian American population has started dispersing gradually throughout different regions in the United States.

Asian Americans represent a number of diverse groups who differ in national origin, ethnic identity, language, culture, religion, socioeconomic background, experiences after arrival in the United States, and length of residence in the United States. For a better understanding of Asian Americans, it is essential to recognize the diversity of the Asian Americans today. Despite their diverse backgrounds, Asian Americans can be categorized into three main subgroups based on their geographic origins: East Asian, Southeast Asian, and South Asian. In the following section, the main characteristics of the three groups are explained.

Asian American Subgroups

East Asian

East Asia generally includes China, Japan, South Korea, North Korea, Taiwan, Hong Kong, Macau, and Mongolia. Among them, Chinese, Japanese, and Korean are the major East Asian ethnic groups found in the United States. Research on the other East Asian ethnic groups in the United Sates is very limited. Chinese, Japanese, and Koreans share the influence of Taoism, Confucianism, and Buddhism, which emphasize interpersonal harmony, social order, a holistic vision of life, and the importance of education. The traditional East Asian families maintain a hierarchical family structure and gender-specific roles. These three groups maintain a high level of educational attainment in the United States.

Despite commonalities among East Asian ethnic groups, they are quite different. Chinese Americans are the largest Asian ethnic group in the United States. Currently, there are more than 2.6 million Chinese Americans living in the United States.

Although Chinese immigrants were among the first Asians to settle in the United States in 1840s, their recent population growth is mainly due to the passage of the Immigration and Nationality Act of 1965. Accordingly, 71% of Chinese Americans in the United States were foreign born. In addition, 85% of the Chinese Americans speak a language other than English at home. Unlike the early Chinese immigrants who were peasants, the majority of recent Chinese immigrants are highly educated and affluent. This demographic shift in the Chinese American population after 1965 has resulted in the polarization of the Chinese community into the working and professional classes. The professional class tends to acculturate well to American society, whereas the working class tends to stay in ethnic enclaves and retain their Chinese traditions.

Similar to Chinese Americans, Japanese Americans were early Asian immigrants in the United States. Although Japanese Americans were the most populous Asian ethnic group between 1910 and 1960, its recent population growth is much slower than the population growth of other Asian ethnic groups in the United States. Accordingly, fewer Japanese Americans are foreign born (40%), and many Japanese Americans are third, fourth, and fifth generations. In addition, Japanese Americans are the oldest Asian American group, with a median age of 42.6 years. The majority of Japanese Americans speak English well. In fact, 53% of Japanese Americans speak only English at home. The poverty rate for the Japanese Americans was the lowest among all the Asian ethnic groups in the United States in 2000. Other data on educational attainment, occupation, and housing suggest that Japanese Americans have a higher level of acculturation compared with other Asian ethnic groups in the United States.

Compared with Chinese Americans and Japanese Americans, Korean Americans have a shorter immigration history in the United States. The majority of Korean immigrants arrived in the United States to seek better employment and educational opportunities after 1965. Many of these recent Korean American immigrants were well educated and from the middle class. The 2000 U.S. Census data indicate that 70% of Korean Americans were foreign born and the majority of Korean Americans speak Korean at home. Several research studies suggest that Korean Americans are more likely to maintain their native culture and participate in ethnic social networks. Their relatively short length of residence in the United States, and the fact that Korean Americans are a homogeneous ethnic

group (speaking one language) who retain their traditional value of education, may largely contribute to their relatively high levels of achievement. In addition, the majority of Korean Americans have strong affiliations with Korean churches, which are primarily Protestant (e.g., Presbyterian, Methodist, Baptist) or Roman Catholic. The Korean churches play a significant role in maintaining their ethnic social networks by providing support and resources for Korean Americans to endure the hardships of acculturation.

Southeast Asian

Southeast Asia generally includes the countries of Cambodia, Indonesia, Laos, Malaysia, the Philippines, Singapore, Thailand, and Vietnam. The most significant characteristic of Southeast Asians is that they are much more ethnically and culturally diverse than East and South Asians. In fact, Southeast Asians with the same national origins can differ greatly in terms of ethnicity, language, and religion. To better understand the Southeast Asian population, it is helpful to distinguish them based on their migration status: Southeast Asian *immigrants* and Southeast Asian *refugees*. More specifically, the purpose of their migrations and the national origins of these two groups have distinctive patterns.

The Southeast Asian immigrants are primarily from Indonesia, Malaysia, the Philippines, and Thailand. Except for Filipinos, who were the only Asians not barred from immigration by the National Origins Quota Act of 1924, most of the Southeast Asian immigrants started migrating to the United States after the enactment of the Immigration and Nationality Act of 1965. The majority of these Southeast Asian immigrants were highly educated and skilled professionals who migrated to the United States to seek better employment.

Among all the Southeast Asian immigrant groups, the Filipinos are currently the largest Southeast Asian immigrant group and the second largest Asian ethnic group in the United States. Many research studies have been done on the Filipino Americans, whereas little is known about the other Southeast Asian immigrant groups. According to these studies, the Filipinos are the most Westernized Asian Americans because of their colonization by Spain and the United States and because of the strong influence of Roman Catholicism. Although the majority of the Filipinos in the United States are foreign born, the Filipinos generally do not have serious language barriers. The Filipino family

structure is slightly different from those of other Asian groups because of the indigenous Filipino culture prior to the Spanish cultural colonization. The Filipino family is more egalitarian, where husband and wife share almost equal power in financial and family decisions. In addition, kinship relationships are highly valued in the Filipino family and play a significant role to provide support for many Filipino Americans in their early stage of adjustment to American society.

In contrast to the Southeast Asian immigrants, the majority of the Southeast Asian refugees arrived in the United States after 1975 following the withdrawal of the U.S. troops from Southeast Asia. They are the newest Asian ethnic group in the United States and their experiences of migration and settlement differ fundamentally from those of other Asian ethnic groups. The Southeast Asian refugees primarily include Cambodians, Laotians, Hmong, and Vietnamese. They migrated to the United States as part of the refugee resettlement program. As political refugees, many of the Southeast Asian refugees experienced traumatic departures from their native countries and spent years in refugee camps in the Philippines, Malaysia, and Thailand before they were admitted to the United States.

Except for the first wave of the Southeast Asian refugees who arrived in the United States in 1975, the majority of the Southeast Asian refugees were less educated and less exposed to Western cultures prior to their migration. In addition, the Southeast Asian refugees were among the youngest Asian ethnic groups in the United States, which is partially due to high birth rates with median ages of less than 20 years for all groups except the Vietnamese. The median age of Hmong in 2000 was 16.3 years. Because of their short history of residence in the United States, the majority of the Southeast Asian refugees do not speak English well. The Southeast Asian refugees are more likely than any other Asian ethnic group to speak a non-English language at home. Although the children in the refugee camps were taught the English language and Western culture, many of them lost opportunities to have a formal education. The 2000 U.S. Census indicates that educational attainment rates for Cambodians, Laotians, Hmong, and Vietnamese were much lower than those of other Asian ethnic groups.

The Vietnamese Americans are the largest Southeast Asian refugee group and the second largest Southeast Asian ethnic group after the Filipinos. Many Vietnamese Americans are ethnically Chinese

who had lived in Vietnam for generations. Therefore, their culture is strongly influenced by Buddhism, Confucianism, and Taoism. Buddhism also strongly influences the Cambodians and Laotians. The Cambodians and Laotians value harmony in interpersonal relations and keep close family relationships. Their societies are characterized by several layers of social classes. The Hmong, one of the ethnic groups from Laos, are strongly influenced by shamanism. Their strong belief in shamanism and their distrust of Western medicine have often created conflicts with social service systems in the United States. Hmong are also known for their strict patriarchal clan system. Many Hmong families maintain close family ties in the United States and geographical concentrations in states such as California and Minnesota. Their acculturation level is much lower compared with other Asian ethnic groups in the United States.

South Asian

South Asia generally includes Bangladesh, India, Myanmar, Nepal, and Pakistan. Although the first wave of South Asian immigrants arrived in the United States in the early 20th century, the majority of the South Asians migrated to the United States after the immigration law was reformed in 1965. Currently, over 1 million South Asians reside in the United States. The South Asian population in the United States consists of a large Asian Indian population, with smaller numbers of Pakistani, Bangladeshis, and other South Asian ethnic groups. The Asian Indians were the fourth largest Asian ethnic group in the United States in 2000. India, Pakistan, and Bangladesh, which were one big colony under British rule, share relatively similar ethnic and cultural backgrounds with the exception of religions. The major religions of the South Asians include Hinduism, Islam, Sikhism, Christianity, and Jainism. Whereas the majority of the Asian Indians are Hindus, the majority of the Pakistanis and Bangladeshis are Muslims.

Similar to other Asian immigrants, the South Asian immigrants consist of highly educated professionals. Many of the recent South Asian immigrants first arrived in the United States as students and later adjusted their status to permanent residents or naturalized citizens. The U.S. Census 2000 indicates that the three major South Asian ethnic groups had exceptionally high college-completion rates. A large number of South Asian immigrants are represented in professional occupations like medicine or other science-related fields. Because

of British colonization, the majority of South Asians speak English fluently. South Asian immigrants, especially Asian Indians, seem to have less trouble with acculturation to U.S. society compared with other Asian American ethnic groups. In fact, Asian Indians are more likely than other Asian immigrants to become naturalized citizens. However, despite their fluency in English and educational achievements, many South Asians suffer from personal and institutionalized racism in the United States. In fact, an increasing number of hate crimes against the South Asians have been reported since the aftermath of 9/11 in 2001. Because of the physical resemblance to people of Middle Eastern descent and the tradition of wearing a turban, Sikh Indians are unfortunately more likely to be targets of hate crimes.

Issues Facing Asian Americans

Model Minority Myth

The image of Asian Americans as a model minority started appearing in the American mainstream media in the 1960s. The term *model minority* was first used in the article "Success Story: Japanese American Style," written by sociologist William Peterson and published in the *New York Times Magazine* in 1960. A similar article using Chinese Americans also appeared in other news magazines in the same year. These articles highly praised the Japanese and Chinese Americans for overcoming hardships and discrimination and achieving success in American society. Thus, the model minority stereotype changed previously held negative images of Asian Americans. Asian Americans are still frequently viewed as a highly successful minority group in the United States. Asian Americans are portrayed as hardworking, highly educated individuals with few psychological problems; this portrayal leads to an inherent assumption that they are less of a burden on American society.

Data Supporting Stereotype

In support of the model minority view, Asian Americans share a great respect for the importance of education. For example, the 2000 census data showed that Asian American parents are more likely to have higher educational expectations for their children than are parents in other race groups. The academic successes of Asian American students have been documented numerous times. In 2000, the college enrollment rate

was 56%, which is higher than other racial groups, including Whites. The proportion of Asian students in Ivy League schools and other top universities in the nation also indicates their academic success in higher education.

In primary and secondary education, this trend also seems to persist. The proportion of Asian American students in gifted classes is much higher compared with their non-White counterparts. The proportion of children who had repeated a grade was the lowest for Asian Americans (2.6% for children 6 to 11 years old and 6.4% for children 12 to 17 years old). Fewer Asian American students between ages 12 and 17 were suspended from schools (5.3%) than White students of the same age span (9.0%). Furthermore, the high school dropout rate of the Asian American students in 2000 (4.0%) was the lowest among all races in the United States.

Data Refuting Stereotype

In sharp contrast to the model minority myth is the fact that the educational attainment data vary greatly by Asian ethnic groups, as discussed previously. One factor influencing these great discrepancies in educational attainment among Asian Americans is their family's migration status to the United States. Whereas many East Asians arrived in the United States as immigrants, most Southeast Asian immigrants arrived as refugees after 1975. Therefore, these two groups differ in terms of parents' level of education and economic status prior to immigration. Many East Asian children have parents with at least bachelor's degrees, whereas many Southeast Asian children have parents who have 9 years of education or less. Accordingly, the household income for East Asians is higher than average, and the poverty rate among Southeast Asian immigrants is higher than average. Educators need to recognize the group differences in educational attainment among Asian American students. Asian American children who have parents with little formal education and moved to the United States as refugees might need additional support at school and at home in order to progress successfully in school and successfully transition to adulthood.

Negative Effects of the Model Minority Myth

The model minority stereotype is a myth that is hurtful to Asian Americans and negatively affects society. Its oversimplification of the Asian American population is misleading and overlooks the great diversity among the Asian American ethnic groups, which is related to the stereotype being created in the 1960s before the recent influx of Asian immigrants and refugees. The increasing heterogeneity and complexity among Asian Americans suggests that the model minority stereotype is creating a great misconception about Asian Americans today.

Still, many non–Asian Americans may think that the model minority stereotype is positive and therefore beneficial to Asian Americans. For example, being considered smart and hardworking is good and may increase one's self-esteem. However, the pressure to succeed academically and to conform to the model minority stereotype has put an excessive amount of pressure on Asian American children and adolescents. Children and adolescents with such pressure from school and society may be more prone to difficulties with anxiety. In schools, Asian American students are often stereotyped as "model" or "successful" students who are hardworking and polite. As a result, the needs of the Asian American students may be frequently overlooked by educators, creating a series of events that may lead to academic and school disengagement and dropout. This becomes especially serious with the Asian American children who are foreign born or who are children of the recent refugees because they need extra support from teachers and other school professionals to adjust themselves to their new school environment. Teachers who believe the model stereotype might expect more from the Asian American students academically. Furthermore, because of the assumption that Asian American students are quiet and passive, teachers might treat them more strictly than they would treat other minority children when Asian American students behave contrary to their expectations.

Finally, in addition to negative education and schooling effects, the model minority myth is frequently associated with false assumptions about racism, poverty, and mental health. The related assumptions are that because of Asian Americans' educational success, their "privileged status" protects them from racism, poverty, and mental health difficulties. On the contrary, these beliefs are false. For example, Asian Americans have historically been the targets of extreme racist acts (e.g., Chinese Exclusion Act of 1882) and continue to experience racism today. One current form of racism is called "glass ceiling,"

which refers to a situation where people are prevented from advancing to higher positions in their careers. The fact that well-qualified Asian Americans are underrepresented in executive and managerial positions suggests the existence of the glass ceiling against the Asian Americans in workplaces. In schools, despite the diversity of Asian American children and adolescents, many Asian American children often experience racism in the form of fighting, name-calling, and teasing because of their race, English proficiency, accent, and foreign attire.

Racism and discrimination are generally exacerbated during economic and national crises. For example, the hate crime statistics reported a sharp increase in hate crimes based on religion and ethnicity/national origin in 2001 after the September 11 terrorist attacks. Asian American Muslims, such as Bangladeshis, Pakistanis, and Indonesians, and South Asians who were perceived to be Arabs or Muslims became the targets of these hate crimes. The hate crimes against Asian Americans included murder, physical assaults, vandalism of places of worship, death threats, and public harassment.

Finally, certain Asian American groups live in poverty and experience mental health difficulties, especially as a result of traumatic immigration experiences.

Identity Development

Identity development for the Asian American is more complex than for someone from the mainstream majority culture because of the negotiation that must occur as a minority person growing up in America with two distinct cultures. As one might imagine, identity development is very important for understanding Asian Americans, which significantly contributes to the diversity among Asian Americans. Two important factors to consider are assimilation and ethnic identity. *Assimilation* refers to the process of becoming Americanized or adopting the American culture. *Ethnic identity* refers to the retention of customs, attitudes, and beliefs of the culture of origin. These two factors represent issues that each Asian American must resolve over his or her life. For example, Bob's actions and beliefs about life may be very similar to the mainstream White European American culture, and he may dismiss the importance of his Asian heritage and have almost nothing to do with it. On the other hand, Bob's sister, Soo, may embrace both American culture and her Asian heritage and feel comfortable with members of each cultural group (bicultural).

ASSESSMENT

Terms such as *measurement, evaluation*, and *test* are sometimes used as synonyms of the term *assessment.* Although these terms are related to assessment, their meanings and purpose are distinctly different. *Measurement* may be thought of as quantifying a performance or characteristic such as score on a test, height, or weight; *evaluation* denotes judgments about the quality or worth of something; and a *test* usually means a specific instrument (paper-and-pencil test) or set of procedures to measure knowledge, abilities, or other characteristics. *Assessment* is a general term that is used to encompass everything a teacher does to ascertain the level at which students have mastered the subject matter, can perform certain tasks, or exhibit certain behaviors.

Assessment includes the collection, analysis, and interpretation of various kinds of information useful for educational decisions. Leonard Carmichael and Bette Caldwell suggested that assessment can

produce direct benefits to students, as teachers use both formal and informal assessments to diagnose students' strengths and weaknesses. Assessment can provide information that helps teachers to identify students who need additional instruction, special services, or more advanced work. Assessment also can serve as the basis for teacher reflections on their instructional effectiveness. Based on data collected though various kinds of assessments, teachers can make instructional decisions about re-teaching a lesson or unit or moving ahead with more challenging lessons. Results of assessments can provide feedback to students to indicate areas in which performance needs improvement and areas in which performance is satisfactory.

Early roots of educational assessment can be traced to the one-room schoolhouse where students moved forward to the next level when the teacher determined they had mastered the necessary knowledge and skills. Tests were administered to ascertain progress, with no letter grades (A, B, C, etc.) reported. Teachers reported student progress orally or through their written notes. The growth of schools necessitated that students be divided into different levels, and percentages were used to report student progress and to identify those who were prepared for college. Comparisons were made among students, and those earning the highest and lowest scores were assigned grades of A and F, respectively. Most of the student scores fell in the middle range and thus were assigned a grade of C for average. Student scores close to the top, but not the highest, were assigned a grade of B, and those falling below the average level were assigned a grade of D. However, in 1912, research by D. Starch and E. C. Elliott raised questions about the use of percentages as a basis for assigning letter grades and screening for college admission. Their research showed great discrepancies in the grades assigned by teachers. This apparent lack of consistency among teachers in grading spurred teachers to use grading scales such as Excellent, Average, or Poor.

In the early 1900s, standardized tests began to be used in the schools as an outgrowth of their use to screen men for the military. Standardized tests were based on national norms. Federal legislation—most notably Public Law (P.L.) 94–142, which mandates a free and appropriate public education for individuals between the ages of 3 and 21; the Individuals with Disabilities Education Act (IDEA), which amended P.L. 94–142; and the No Child Left Behind (NCLB) Act—has brought about increased interest in assessment at the local, state, and national levels.

Behavioral Objectives

Benjamin Bloom, Professor of Education at Chicago University, working with his mentor, Ralph Tyler, believed that the importance in education was whether or not students achieved what they were studying, not how they were compared with others. Bloom believed that the environment is influential to a child's success in school. He believed that it was the educator's responsibility to create an environment to serve students at various ability levels. Bloom suggested that human learning could be classified into three major domains: cognitive, affective, and psychomotor. Bloom and a group of his colleagues began development of a system to describe behaviors in the cognitive domain in 1948 and development of a classification system for the affective domain in 1956.

Each domain comprises levels that range from the lowest level of learning to the highest. This classification of learning is commonly known as "Bloom's Taxonomy of Learning" or simply, "Bloom's Taxonomy." Classification of learning domains serves several purposes. They help to assure that teachers know the objectives of the lesson and stay focused on the intended outcomes, to direct students to the objectives of the lesson, and to serve as a basis for identifying the kinds of knowledge, skills, and attitudes that will be assessed. The knowledge, skills, and attitudes are usually stated in the form of instructional (behavioral or performance) objectives to communicate clearly the student's required performance, the conditions or circumstances under which the performance will take place, and the standard or criterion that will be used to assess whether or not the student has achieved the objective satisfactorily.

Types of Assessment

Student achievement may be assessed with standardized tests or teacher-made tests. A standardized test covers a broad knowledge base rather than knowledge associated with selected lessons or a specific unit of instruction. Uniform administration procedures are required in which the directions are standardized, and all students get the same or an equivalent test under the same conditions for the same amount of time. Interpretation of the results for a specific student is

based on that student's performance compared with the performance of other students at the same grade level. This is known as *norm-referenced testing.* Normative tables showing the relative performance of a student compared with that of other students in the norm group are usually provided by the test developers for standardized tests. Because one student is compared with other students in the norm group over a broad knowledge base, it is not sound educational practice for teachers to use standardized test scores as a basis for assigning class grades. Standardized tests are used best to show parents or school personnel how one student compares with other, similar students. For accurate and meaningful comparisons to be made, it is important that the norm group be representative of the student with whom comparisons are made.

Teacher-made tests are used to assess student achievement over a specific body of knowledge taught in the classroom. Teacher-made tests are known as *criterion-referenced tests.* The performance of one student is not compared with that of the group; instead, each student's response to a specific question is measured against a predetermined criterion. Clearly defined instructional objectives provide the foundation for criterion-referenced classroom assessment. In turn, criterion-referenced classroom assessments are used for the purpose of identifying the extent to which students have achieved the objectives.

Student achievement is assessed with a variety of tests and test item formats. Objective test items are commonly used to assess performance because they can be written to test higher as well as lower levels of learning and to test a broad range of subject matter. Objective tests are easily administered and scored. Scoring is more objective than in most other kinds of test items; consequently, fewer scoring errors are made. Objective test items require that students write or select a response. Written responses may be short answer or completion. Commonly used selected response items include multiple-choice, true/false or alternative response, and matching. Although objective tests remain a favorite among teachers, alternative methods of assessment are gaining in popularity. Performance ratings, essays and products, portfolios, and service learning are popular forms of alternative assessments.

Some instructional objectives require that students engage in an activity to demonstrate their level of skill. For example, athletic or musical skills cannot be assessed appropriately with a paper-and-pencil test.

The teacher will want to assess students' speed, timing, and precision as they demonstrate cognitive, psychomotor, and affective behaviors. Sequence of events is an important consideration when assessing an individual's ability to operate a motor vehicle, and quality of presentation is important when assessing the overall effectiveness of an individual's oral report delivery. Performance assessments are time consuming to administer because only one student can be assessed at a time. Also, the teacher must be keenly attentive to the performance in order not to miss important but rapidly performed steps. Rubrics such as checklists and rating scales are used to ascertain the effectiveness of the performance.

Some instructional objectives require students to construct individual and unique responses to demonstrate their competence. Responses may be in the form of a written essay or a product. Essays and products typically incorporate higher-order thinking skills in analysis, synthesis, and evaluation. A written essay, for example, may require that students critique a procedure, event, literary work, or political or philosophical view. Creating a product requires planning, organizing, and actually producing a tangible result such as a poem, play, blueprint, computer program, or birdhouse. Essays and products are time intensive for teachers to plan and score because of the individual nature of the products. Responses must be scored by an expert teacher who can ascertain whether or not responses are accurate and acceptable.

Portfolios are an excellent way to document and communicate student progress over time. Samples or exhibits of a student's initial work are usually included in the portfolio, and other exhibits are added throughout the grading period or the course. Exhibits may include accomplishments and deficiencies that are not directly related to instructional goals. For example, exhibits may include selected test scores, notes related to attitudes and behaviors that are not evident on report cards, social accomplishments, special projects, interest inventories, and interviews. Exhibits included in the portfolio are often used to supplement other kinds of assessment.

Service learning is gaining in popularity as an alternative teaching and assessment tool because it requires students to demonstrate their knowledge, skills, and attitudes in real-life situations. Students are involved in activities designed to meet instructional goals while providing a useful service to the community. The purpose of service learning is to improve

academic learning while enhancing personal skills and civic responsibility through structured projects that serve a real community need.

Item Analysis

An *item analysis* provides information about the difficulty of a test and the extent to which a specific test item discriminates among the test-takers in the same way that the overall test discriminates. Item analysis may be performed by a computer program or hand calculated by classroom teachers.

Item Difficulty

An item difficulty index is a statistical procedure that indicates the proportion of students who responded correctly to an item. The closer the index is to 1, the higher the proportion of students who responded correctly to that item and the easier the item. The term *item difficulty index* is referred to in many sources as the *item easiness index* because it refers to the percentage of students responding correctly to a specific item. Calculating this index requires that the test items for the high scoring students and low scoring students be separated from those whose scores fell in the middle range. Depending on the total number of students, this may mean using the top 25% and the bottom 25% in the analysis. If the total number of students is small, then all students may be used in the analysis by grouping students in either the high scoring or the low scoring group. The difficulty index is then calculated by adding the number in the high scoring group who got the item correct to the number in the low scoring group who got the number correct and dividing the sum by the total number of students.

Item Discrimination

Item discrimination is a statistical procedure that indicates the extent to which an item discriminates between high scoring and low scoring students on a specific test item in the same way that the total test discriminates between those who know the content and those who do not. This procedure also requires that the test items for high scoring students and low scoring students be put into separate groups. If an item discriminates adequately between the high scoring group and the low scoring group, students in the high scoring group should get a specific item correct more often than students in the low scoring group. A negative (and undesirable) discrimination would result if students in the high scoring group missed an item more often than students in the low scoring group. An item discrimination index may be calculated by subtracting the number of correct responses on one item of students in the low scoring group from the number of correct responses of students on the same item in the high scoring group and dividing this difference by the number of students in one of the groups. The resulting discrimination index will be between 0, indicating no discrimination, and 1, indicating perfect discrimination between high and low scoring students on an item. An index close to 1 indicates high discrimination between the two groups on a specific item, and thus, this is the more desirable item.

An item analysis provides insight into the way specific items function within a test. Such an analysis can help teachers to increase the reliability and validity of their tests. In addition, the analysis can provide teachers with information regarding items that are hardest for students, which are easiest, and where adjustments in content or the teaching process need to be made. In their book *Instructors and Their Jobs*, W. R. Miller and M. F. Miller illustrate statistical procedures useful for teachers conducting an item analysis.

Test Reliability

Reliability and validity are two important concepts in assessment. *Reliability* refers to the consistency or stability of a test in producing the same or similar scores over repeated administrations of the test. For example, if a student scores high or low on a test of word comprehension in the morning, then one should expect that if the same or a similar test were administered in the afternoon, the student would have the same or a similar score providing that no changes were made in the student's level of knowledge or administration of the test to bias the results. If the two administrations of the test yielded the same or similar results, then the test would be reliable; however, if there were a great discrepancy between the two administrations, then the test would be unreliable. Reliability is affected by different sources of error, which are called random errors. Variations due to individual attributes such as general knowledge, ability, skills, motivation, health, and attention are all sources of error. In addition, random errors may be due to variations in the characteristics of the test.

A test that is too short gives an advantage to students who happen to know the correct answer to a few questions, whereas students who actually have a broader knowledge base may not know the answers to the few questions asked. It is valuable for educators to know the amount of true variance (spread of a set of scores) and error variance reflected in a particular test score. In educational testing, it is assumed that every observed test score has a true score component and an error score component; the variance of the observed score is equal to the variance of the true score plus the variance of the error. However, in practice, a true test score is impossible to calculate because one would have to administer a test an infinite number of times. If this were possible, the sum of the errors and the mean of the errors would be 0. Theoretically, the true score for one individual is the average score obtained from repeated measures; it is considered to be somewhere between plus and minus a certain margin of error, called the standard error of measurement (SEM). The SEM is derived from the standard deviation of the sampling errors. This concept is illustrated by a student who scores an 80 on a mathematics achievement test and the SEM is 3.2. The student's true score is said to fall somewhere between 76.8 and 83.2. A common practice to determine stability of test scores is to compute a coefficient of correlation, known as a reliability coefficient, between two independent administrations of the same test to a large sample within a reasonable time period between administrations (test–retest reliability coefficient or coefficient of stability). Other procedures to ascertain reliability are (a) correlating the scores of alternate forms of the same test administered in succession to a large group (coefficient of equivalence) and (b) correlating the scores on equivalent forms of a test given in two independent administrations over a short period of time (coefficient of stability and equivalence). The reliability coefficient ranges from 0, indicating no reliability of the test, to 1, indicating perfect reliability.

Different reliability procedures are required to ascertain the extent to which all items in a test are measuring the same information. This is known as the internal consistency of a test. The split-half technique is a commonly used procedure to determine internal consistency. This involves administering a test, dividing the items independently into two equivalent halves, and computing the correlation coefficient between the two halves. The Spearman-Brown statistical procedure is used to calculate internal consistency using split-halves. Kuder-Richardson formulas 20 and 21 and Cronbach alpha are useful for assessing the homogeneity of items within a test. These latter procedures do not require splitting the test; rather, they are based on properties of the entire test.

Developing reliable tests is a challenge, and obtaining perfect reliability is impossible or difficult at best. Reliability is affected by the difficulty level of the test. A test that is too difficult or too easy can be reliable in that similar outcomes result. However, in the case of a test that is too difficult, the test provides chance results, and in the case of a test that is too easy, the test would not yield meaningful results. However, teachers can improve reliability by (a) creating a positive test environment, (b) allowing enough time for students to complete the test, (c) selecting or constructing tests that cover a representative sample of the content, including enough items to test the breadth of the content, and (d) including test items that discourage guessing so that students' scores remain stable from one administration of a test to another or from one form of a test to another. Reliability is concerned with the stability of test scores over time, and even though classroom teachers do not generally calculate the reliability of their tests, test developers are expected to assess and report the reliability for all standardized tests. Reliability is a necessary requirement for validity.

Test Validity

Validity is the extent to which a test measures what it was designed to measure. This means that tests are designed for specific purposes, and each test must have its own validity for the purpose for which it was designed. A valid test must also be reliable; however, the converse is not true. Reliable tests are not necessarily valid. That is, a test may consistently measure the wrong thing. Establishing test validity is thought to be a more complex process than establishing test reliability because establishing validity depends on the judgments to be made based on test results and how the results will be used. It is necessary to collect information as evidence that a test provides a true measure of such abstractions. To validate that tests provide true measures, certain information or evidence must be collected depending on the type of validity to be determined. Three common types of validity are content validity, criterion-related validity, and construct validity.

Content Validity

Assessing an individual on the complete domain of a knowledge base related to a specific subject is not usually feasible. Therefore, the typical procedure is to assess only a sample of the knowledge base. For example, teachers do not purport to ask students every possible question about a topic on a classroom test. They select a sample of test questions from which to make inferences about the students' grasp of the subject matter. Content validity is concerned with the extent to which the sample of questions is representative of the knowledge base being tested. If experts in the content area to be tested agree that the test questions are a representative sample of the knowledge base to be tested, the test is said to have face validity. Logical validity is closely related to face validity, except in establishing logical validity, all the behaviors to be measured within a specific knowledge base need to be identified and defined. Then, test questions are designed purposely to test the desired knowledge base. Content validity is established through rather subjective techniques; consequently, the potential for error is greater than in criterion-related or construct-related validity. Also, it is important that users of a test, especially achievement tests, understand the knowledge base that the test was designed to assess. Nonetheless, content validity is important to the development of all tests, and other kinds of validity are established more confidently when a test has content validity.

Criterion-Related Validity

The extent to which scores on a test correlate with an independent external variable provides evidence related to criterion-related validity. The independent external variable is the criterion that is thought to be a direct measure of the attribute of interest. For example, college admission tests are thought to be valid predictors of success in school as denoted by grade point average. The test to be validated is administered and scores are held until the criterion scores are available. Next, the scores on the college admissions test (predictor) are correlated with grade point average (criterion). The greater the correlation is between scores on the admissions test and the grade point average, the stronger the criterion-related validity is. This is referred to as predictive validity. The more accurately a test predicts is directly related to the strength of the correlation between the scores on the predictor test and the criterion.

Concurrent validity can be determined by correlating scores on a measuring instrument to be validated with a current score. A correlation coefficient is calculated as in predictive validity; however, the difference between predictive validity and concurrent validity is that in concurrent validity, the test to be validated is correlated with current scores on some measure. For example, the correlation of scores on a standardized mathematics test with students' current grades in mathematics provides concurrent validity. Concurrent validity is most useful for diagnostic purposes or assessment of current status.

Construct Validity

Construct validity refers to the extent to which a test measures a theoretical variable (construct) or trait. Many variables of interest in educational research are abstract. For example, intelligence, motivation, interests, self-concept, and self-efficacy are abstractions for which researchers must determine appropriate indicators that will give an assessment of these attributes. Establishing construct validity is an ongoing process, and several different procedures may be used for this process. Empirical data can be used to indicate the extent to which items on the test represent the construct. Positive correlations among items on the test and positive correlations between scores on the test and other valid observations indicate that the items include the elements predicted by the construct. Extremely low or negative correlations are indicators that the test items do not represent the construct or that an inappropriate construct is being measured. In addition, visual inspections of the items and questioning the intent of each item can help to ascertain the extent to which the items represent the construct.

ASSISTIVE TECHNOLOGY

As technology is reinvented to make everyday functions easy, its marriage with assistive devices significantly affects the life of individuals with disabilities. This technology is referred to as *assistive technology (AT).* Assistive technology, including assistive, adaptive, and rehabilitative devices, aids individuals with disabilities in achieving greater independence and self-confidence in their daily lives; specifically, AT enables individuals with a range of cognitive, physical, or sensory impairments to have alternative ways of performing and participating in society. AT also assists in communication, information processing, education, work, and recreation activities.

The importance of AT in the lives of people with disabilities was pointed out in the Individuals with Disabilities Education Act (IDEA; also called the Tech Act) as "any item, piece of equipment, or product system, whether acquired commercially off the shelf, modified, or customized, that is used to increase, maintain, or improve the functional capabilities of a child with a disability" [P.L. 108–446, Title 1, Part A, § 602(1)]. According to this definition, AT encompasses a wide range of devices from low-tech supportive tools such as battery interrupters to high-tech advanced and customized electronic equipment such as computers. AT can include mental aids, communication aids, alternative computer access, visual aids, or aids to augment hearing to increase the involvement of persons with disabilities in learning activities.

Through IDEA, AT can be utilized in educational settings with a new assigned term, *special education technology,* to provide students who require a differentiated instructional treatment with increased and independent learning opportunities. Appropriate AT services can also be offered in free public education.

IDEA highlights AT services, aiming to enable students to have full inclusion and least restrictive environment in schools. This law defines AT service as "any service that directly assists an individual with a disability in the selection, acquisition, or use of an assistive technology device" [P.L. 108-446, Title 1, Part A, §602(2)]. This service includes the following:

- The evaluation of the technology needs of the individual with disability, including a functional evaluation of the individual in the individual's customary environment
- Purchasing, leasing, or otherwise providing for the acquisition of AT devices by such individual
- Selecting, designing, fitting, customizing, adapting, applying, maintaining, repairing, or replacing of AT devices
- Coordinating and using other therapies, interventions, or services with AT devices, such as those associated with existing education and rehabilitation plans and programs
- Training or technical assistance with AT for such individual, or, when appropriate, the family of such individual
- Training or technical assistance for professionals including those individuals providing education and rehabilitation services

The intention of IDEA is that AT devices and services must be provided at no cost to the student, student's parents, and the school staff as part of the student's special education, related services, or supplementary aids and services to facilitate the student's education. However, the school may use whatever state, local, federal, and private resources are available.

Advocates of AT list the individuals who might benefit from special education technology:

- Individuals with mental or physical impairments that interfere with learning or other life functions
- Individuals with mild learning or cognitive problems like learning disabilities or cognitive disabilities ranging from mild to severe that interfere with learning or other life functions

Because AT has demonstrated an ability to provide individuals with disabilities opportunities that fit into their individual needs and abilities, the appropriate

use of AT may be delineated when it enables the individual to do the following activities:

- Perform functions that cannot be achieved by other methods
- Approximate normal fluency, rate, or standards—a level of accomplishment which could not be achieved by any other means
- Participate in programs or activities which otherwise would be closed to the individual
- Complete tasks that otherwise are too laborious to be attempted on a routine basis
- Concentrate on learning or employment tasks rather than mechanical tasks
- Have greater access to information
- Have normal social interactions with peers and adults

There are approximately 20,000 AT devices currently available. These can be located through online resources such as Abledata, which is supported by the U.S. Department of Education. Because of the large number of available AT devices, specialists and professionals must give thoughtful consideration to the selection and procurement of appropriate devices for impaired students. AT devices and applications include various types of accommodations and adaptations that enable individuals with disabilities to function more independently and confidently. The following section lists and categorizes common AT devices and applications based on individuals' impairments.

Assistive Technology Devices

Communication

In this category are devices or equipment designed to help individuals with speech disabilities or writing difficulties (e.g., no or very little verbal skills, limited language proficiency, etc.) to communicate effectively and to have alternate methods of communicating needs, feelings, ideas, and perceptions. Speech and augmentative communication devices include on-screen communication boards, auditory or visual scanning, speech synthesizers, text-to-speech software and hardware, head wands, light pointers, mouth sticks, signal systems, telephony equipment, and talking word processing with writing support. Writing and typing devices include tactile devices, Braille devices, note-taking devices, spelling devices, word prediction/completion software, modified typewriters, portable typewriters, and electronic and software dictionaries.

Access

These hardware and software products enable individuals with barriers to access to interact with learning tools and engage in classroom or home activities. *Alternative input devices* include alternative and adaptive keyboards, expanded keyboards, keyguards, alternative and ergonomic mouse/pointing systems, head-operated pointing devices, eye-gaze pointing devices, mouth/tongue pointing devices, Morse code input devices, brain-actuated pointing devices, switches, touch screens, voice input systems, speech-to-text software, voice recognition/voice command software, dictation software, on-screen keyboards, cursor enlargement software, ergonomic computer-based equipment, scanners and optical character recognition, joysticks, and trackballs. *Processing devices* include abbreviation/expansion and macro programs, access utilities, menu management programs, reading comprehension programs, writing composition programs, and writing enhancement tools. *Alternative output devices* include Braille display/output devices, Braille embosser/printers, screen-reading software, screen magnification/enlargement software, large print monitor, and speech synthesizers. *Accessible software* includes software applications adapted for individuals with disabilities, operating system accessibility options, and accessible web browsers. *Universal design* (also called *design-for-all* or *accessible design*) includes design methods, techniques, and guidelines for making computers and their applications fully accessible to individuals with disabilities.

Learning and Studying

These devices help individuals with high-incidence disabilities (learning, behavior, or cognitive disabilities) to increase, maintain, or improve their functional capabilities. Such devices include Post-It™ notes, picture or written schedules, social stories, written or picture-supported directions, and editing devices (e.g., correction fluid, correction tape, correction pen, highlight tape, etc.), sentence windows, graphic organizers, single-word scanners (reading pens) or handheld scanners, portable or talking word processors, handheld computers, voice-recognition products, software for organizing ideas and studying, electronic organizers or reminders, word-prediction software, talking electronic device or software to pronounce challenging words, graphic organizer software, software for

concept development, manipulation of objects, math computations, portable word processor to keyboard instead of write, closed-captioning television, text-reading software, and tactile or voice-output measuring devices.

Vision

Products designed to assist the blind and visually impaired individuals include auditory and speech output devices, reading machines, scanning/document reading systems, optical character recognition (OCR) systems, electronic book readers, talking equipment (clocks/watches, calculators, etc.), Braille devices, Braille transcription and translation devices, screen magnifier/enlarger, closed circuit television for magnifying documents, book holders, manual and electric page turners, large button phones, speaker phones, large-print books, taped/audio books, light boxes, high contrast materials, thermoform graphics, synthesizers, scanners, and descriptive video services.

Hearing

Products designed to assist individuals who have deaf and hearing impairments and/or auditory processing problems include assistive listening devices, hearing aids, infrared/personal amplification systems, audio/FM loop systems, FM amplification systems, TV amplifiers, TV decoders, visual signaling and alerting systems, tactile alerting systems, telephony and accessories, text telephones, telecommunication devices for the deaf (TDD), teletypes (TTY), adapted phones, real-time captioning, telecaption decoders, and cochlear implants.

Daily Living

Self-help devices that assist persons with disabilities in daily living activities, such as dressing, personal hygiene, bathing, home maintenance, cooking, and eating, include reaching devices, adaptive clothing, modified eating utensils (e.g., specialized spoons for self-feeding), feeding accessories and devices, adapted books, pencil holders, time management aids, dressing aids, adapted personal hygiene aids, bathing accessories, grab bars/grips/handles, incontinent supplies, mechanical transfer lift, shower/bath chair, toileting accessories, transfer board, wheeled bath chair/commode, and bathtub seats.

Environment

The use of these aids and equipment help to remove or reduce physical barriers for individuals with disabilities in educational and workplace settings. *Environmental controls and switches* are primarily electronic systems that enable someone with limited mobility to control various appliances, lights, telephone and security systems in their room, home, or other surroundings. These systems include environmental control units, electronic appliance switches, switch mounting systems, home automation systems, signaling and alerting devices, home alarms, television adaptations, smoke alarms, and telephone ringers. *Home-workplace adaptations* include worksite/school/home design or modification for accessibility, architectural accommodations, structural adaptations, building/home ramps, home elevators, wheelchair lifts, pool lifts, bathroom changes, automatic door openers, expanded doorways, adapted furniture, adapted doorknobs, alternative doorbells, lowered counters, and specially designed bath areas.

Ergonomic Equipment

Ergonomic equipment is low-tech assistive equipment or devices designed to reduce the likelihood of repetitive stress injuries often associated with work-related situations. These devices include adjustable workstations, industrial workstations, office workstations, adapted furniture, writing aids, modified seating and lighting, arm/wrist supports, and back supports.

Mobility and Transportation

These products help mobility-impaired persons move from one place to another and give them independence in personal transportation. Such products include standing/walking aids, transfer aids, stair lifts, walkers, scooters, wheelchairs and three-wheeled chairs, adapted bikes and tricycles, car seats, beds, stretchers, patient chairs, ramps, recliners, strollers, travel chairs, wheelchair trays, driving controls, seat belts, vehicle conversions, patient and wheelchair lifts, wheelchair loaders/carriers, and wheelchair restraint systems. Ambulatory aids include canes, cane accessories, crutches, walkers, and walker accessories. Vehicle conversions include car-top carriers, custom cars and vans, adaptive driving controls, hand-controls, child restraint systems, ramps, and lifts.

Prosthetics and Orthotics

Prosthetics and orthotics serve to replace, substitute, or augment missing or dysfunctioning body parts with artificial limbs or other aids. These devices include splints, braces, foot orthoses, helmets, restraints, and supports.

Recreation and Leisure

These products help persons with disabilities to participate in sports, social, and cultural events and interact with their peers without disabilities, which allow disabled people to focus less on individual differences. Such products include adaptive sports equipment for skiing, biking, swimming, running, boating, adaptive music with symbols, adaptive controls for video and table games, adaptive fishing rods, cuffs for grasping paddles or racquets, and seating systems for boats.

Seating and Positioning

These products assist impaired individuals in maintaining body alignment, upright posture and trunk/head support, and reducing pressure to the skin. Such products include adapted and modular seating, cushions and wedges, contour seats, lumbar support seats, standing tables, positioning belts, braces, wheelchair modifications and cushions, seat lifts, bolster chairs, corner chairs, therapeutic seats, postural support hardware, postural support systems, and pressure monitors.

ATHLETICS

College athletics in the United States has prospered significantly since its inception. It has also been faced with controversy ranging from threatening the academic integrity of higher education to extreme levels of commercialization. Regardless, college athletics has provided millions of students with opportunities to not only compete in athletics but also achieve an education and ultimately a college degree. This entry examines college athletics in higher education. It uses both historical and sociological sensitivities to provide a conceptual framework for this analysis. These sensitivities provide a historical context to understand the origin and development of college athletics and a sociological context to understand how college athletics has evolved into a social spectacle that provides millions with a source of entertainment and a cultural event that inform their daily life.

Origin and Governance of Men's and Women's College Athletics

College athletics has a very modest beginning. The origin of college athletics dates back to the Gilded Age during 1865–1900. It began as student-controlled sporting opportunities for members of the university student body, and because the sports were not sanctioned by the institution, they did receive financial support. As these activities became popular and profitable enterprises, alumni, faculty, and administrators took control, which created a shift from college athletics being informal, student-controlled activities to formal, university-sanctioned events; this move from informal to formal required additional administrative and governance structure to oversee these events.

A major part of college athletics history is the development of its organizational and governance structures. Therefore, a major transition to denote a shift in college athletics took place in 1905 when President Theodore Roosevelt summoned 13 institutions to the White House to address the need for athletic reform, more specifically, the need for rule changes in the game of football. Thus, the Intercollegiate Athletic Association of

the United States (IAAUS) was formed by 62 institutions to address additional concerns that emerged since the inception of college athletics. In 1910, the IAAUS changed its name to the National Collegiate Athletic Association (NCAA) and continued to grow beyond its initial origins of being an advising and rule-making association and sought to address several issues that were challenging the very nature of college athletics.

For example, due to the increase in popularity and profit of college athletics, issues regarding academic integrity, professionalization, institutional control, and the safety of players were major concerns that created a need for athletic governance. College athletes at several major schools, at this time, were basically recruited to play sports; thus, the academic integrity and mission of the institution was being challenged. The increased popularity also gave athletic departments unlimited freedom in operating beyond the educational philosophy of the university, which required a need for greater institutional control where all departments associated with the university would ultimately report to the university's president and comply with the educational mission of the institution. Finally, several deaths occurred during football competition due to game rules and equipment.

College athletics faced growing pains due to expansion in membership and an increase in postseason championship games. It was not until after World War II that issues concerning recruiting and financial aid were addressed whereby standards were being established to minimize athletic deviance. However, the NCAA continued to face challenges that required professional governance and a shift from part-time leadership to full-time leadership. In 1951, Walter Byers became executive director and began to chart a new course for the member institutions, in which the NCAA, on behalf of its member institutions, would gain control over live television coverage of football games and postseason bowl games.

Governance for women's athletics had a different philosophy than that of men's. Although women's athletics has been around as long as men's athletics, it did not receive equal support, and women did not have a wide variety of sports to compete in at the collegiate level. Both men's and women's athletics had strong connections with university physical education departments; however, women's sports governance adhered to more a process orientation rather than outcome orientation. In other words, competing in sports was about the process of learning desirable skills and abilities and not solely about winning. Women's athletics was less commercial and did not initially offer scholarships or recruit outside of the respective institutions' student bodies.

The organization of women's athletics on the national level did not take place until 1941. Its first national championship game was in the sport of golf. As women's athletics began to increase and colleges across the nation began organizing women's sports teams, the need for additional governance increased. It was during the late 1950s and early 1960s that a committee with representatives from three organizations (the National Association for Physical Education for College Women, the National Association for Girls' and Women's Sports, and the American Federation of College Women) consolidated its forces under one organization called the Division for Girls' and Women's Sports, and from this consolidation the National Joint Committee on Extramural Sports for College Women was formed, with the primary responsibility governing women's intercollegiate athletic programs. From this committee, the Commission on Intercollegiate Athletics for Women (CIAW) was formed in 1967 with two major purposes: (1) to provide a structure and governance of women's collegiate athletics, and (2) to oversee and sponsor national championships for women collegiate sports. However, in 1971, the Association for Intercollegiate Athletics for Women (AIAW) evolved from the CIAW and became the governing body for women's athletics.

Throughout the various levels of consolidating and organizing, women's sports continued to grow in membership, to around 280 schools, and in championship games played at the national level. What assisted in the growth and support of sporting opportunities for women and girls, especially women at the collegiate level, was the passing of Title IX of the Education Amendments in 1972 by the Congress of the United States. Title IX was enacted to prevent federally funded institutions from denying support and benefits and/or discriminating on the basis of sex. Although Title IX applied to all educational activities, it had significant impact on the increase in girls' high school and women's collegiate sports. To ensure its proper implementation in the area of sport, a three-prong test was developed to inform institutions of their compliance. The following questions were posed: (1) Are athletic opportunities substantially proportionate to the student enrollment? (2) Is there evidence of consistent growth of athletic opportunities for the previously marginalized gender? (3) Is there

complete and effective accommodation of the interest and ability of the previously marginalized gender?

Ultimately, despite the fact that the AIAW had around 1,000 members during its governance of women collegiate athletics, when the NCAA decided to offer women's championships, it threatened the AIAW's existence. When the NCAA began to offer incentives packages to women's teams participating in championship games, the AIAW began to lose its status and popularity. One major misfortune to the AIAW was when the National Broadcasting Corporation canceled its contract with the AIAW, causing many schools to participate in the NCAA's national tournament instead. After failed attempts to sue the NCAA for its attempts to monopolize collegiate sports, the AIAW ceased to operate in 1982.

With the merger of women's and men's collegiate sports under the governance of the NCAA, athletic departments witnessed an increase in scholarships and larger recruiting and operating budgets. Furthermore, despite the growth of both women's and men's collegiate athletics, several problems emerged from this merger regarding equitable treatment and support for women's athletics. Thus, there has been a continual need for women's sports to seek to enforce the guidelines of Title IX, which is also referred to as gender equity, to ensure equitable treatment.

The origin and governance of collegiate athletics has been a long and winding road to its current destination at this point in history. From its humble beginnings, collegiate athletics has grown into a multibillion-dollar industry with multiple streams of income deriving from the sales of broadcasting rights; sponsorship; collegiate licensing merchandise; naming rights of stadiums, arenas, and championship events (including bowl games); and more.

The Role of the Athlete in Higher Education

A key area to address in the growth of college athletics is the role of the athlete at the collegiate level, which has changed considerably since the first intercollegiate athletic competition. Initiated originally as extracurricular or intramural activities, some of these competitions have evolved into multimillion-dollar spectacles. Once events intended to break the monotony of the rigorous academic pursuit, these competitions, especially in basketball and football, have become main staples and major attractions at many collegiate institutions in the United States. Thus, the athlete has evolved from simply a leisurely participant in these competitive engagements to an athletic celebrity on campuses throughout the United States.

To further distinguish the role of the athlete in college athletics, it is important to examine the major divisions of competition within the NCAA, as it comprises 1,025 members at different divisions and subdivisions. Another, smaller collegiate athletic governing body is the National Association of Intercollegiate Athletics, which has about 282 members and is considered more amateur than the NCAA in its role and philosophy. The major level of athletic competition is Division I-A, which comprises 119 members. Some of the basic requirements for institutions to hold membership at this level are that they must fund at least seven men's and women's sports or six men's and eight women's sports; they must also have at least two team sports for women, and each playing season must have a fair gender representation. Another basic requirement is related to the scheduling of events and the participant minimum for each sport.

These NCAA Division I institutions are the top-tier athletic programs in the country, and the athletic operating budgets of the top 20 of these institutions range from $32 to $75 million. They sponsor football programs with stadiums that seat 60,000 to 100,000 people and basketball arenas that range in seating from 10,000 to over 25,000 people. These programs operate like corporations, where athletic talent is the major commodity. These programs require a premium on athletic talent; thus, they spend a significant amount of time and money recruiting the best athletes. This form of corporate athleticism or athletic capitalism places the athlete within controversial and sometimes diametrically opposing roles, especially in revenue-generating sports (i.e., football and basketball). High-level athletic demands often place academic demands as a lower priority. Being both a student and an athlete creates challenging roles that require a healthy balance that many young men and women competing in intercollegiate athletics learn to master effectively.

Graduation rates are often the determining factor to whether athletes are successfully balancing the role of student and athlete. At this level, the NCAA reported in 2006 that athletes graduated at a rate of 77%, whereas the regular student body graduated at a rate of 61%. The revenue-generating sports of football and men's basketball have had the lowest graduating rates, at 55% and 45%, respectively. Black male athletes

were reported as graduating at 49% in football and 38% in basketball. Women, especially White women athletes, and White male athletes fare better than their Black male counterparts at balancing the role of student and athlete and continuing on to graduation.

One of the factors affecting graduation rates for athletes in the sports of football and basketball is early departure into professional sports. These early departures count against the institution, thus lowering its graduation percentage rate. Despite the age limit restriction instituted by the National Basketball Association and the National Football League's restriction on not allowing underclassmen the opportunity to compete until a minimum of 3 years after their high school graduation, many athletes have turned professional without the reward of graduating with a degree. Intercollegiate basketball has been a victim of athletes spending only one or two semesters on campus before entering the draft. This gives them enough time to meet the minimum age requirement but unfortunately alters graduation rate calculations.

One of the remedies for the low graduation rates among athletes in sports that generate millions of dollars a year in revenue is the Academic Progress Report (APR). The APR was designed to assist in reforming college athletics by improving academic success and graduation rates among athletes. It is calculated whereby one point is given to a team each term a scholarship athlete meets the required academic eligibility standards; an additional point is given if the athlete remains with the institution. A cutoff score of 925 corresponds to graduating 59% of scholarship athletes. If a team does not meet the cutoff on what the NCAA refers to as a basis that is statistically significant, the university can be penalized by losing a scholarship in that sport.

The need for athletic reform speaks to the demand athletes have had in balancing the roles of student and athlete. It also speaks to the incongruence many critics see between the earning of millions of dollars off the blood, sweat, and tears of young vulnerable men and women and the lack of academic integrity demonstrated each year when institutions are exposed for academic fraud. Athletics at other divisions have not suffered the same criticism because of fewer demands to generate revenue.

The next collegiate levels of athletic competition are the Division I-AA and I-AAA levels. At the Division I-AA level, which consists of 116 members, the athletic programs are considerably smaller. There are

91 members at the Division I-AAA, and these institutions do not have football programs. However, they compete in a variety of other men's and women's sports.

The next level within the governance of the NCAA is Division II, which comprises 281 members. These members must fund a minimum of five sports for men and five for women or four for men and six for women. Similar to Division I members, Division II members must also have a minimum of two team sports for each gender and have fair gender representation for each playing season. One of the major differences between Division I and II is that financial support for students at Division II schools is generally a combination of money from scholarships, grants, and student loans, whereas Division I schools are able to provide full athletic scholarships to more athletes. Therefore, the range of students being recruited is limited to state and local athletes for most Division II schools, whereas the range for recruitment at Division I schools is greater— including national and international recruitment of athletes. The role of the Division II athlete is less labor intensive than the role of the Division I athlete.

The final level to discuss is Division III member institutions. There are currently 420 institutions that are members at this level, which makes it the largest division governed by the NCAA. These institutions are relatively smaller in student body population than the other two divisions: 500 to over 10,000. One of the differences between Division III and Divisions I and II is that Division III member institutions do not offer any athletic-related financial aid. At this level, the sports are considered extracurricular activities for the student body population; thus, they do not generate revenue. Athletic participation at this level is considered purely amateurism by many critics of college athletics. Because athletes do not receive any financial aid or endowments, they are basically pursuing athletics for no financial benefit. Thus, academics are generally the primary focus of the student, and athletics is secondary. The major reason is that very few athletes become professional athletes from this division. Therefore, the philosophy of these programs is more process oriented instead of outcome or profit driven; it is for the love of the game.

Future Directions

College athletics has evolved into a profitable industry that has combined the pursuit of athletic excellence with the academic mission of institutions of higher learning.

At the NCAA Division I level, the challenge has been in operating revenue-generating activities within a non-profit entity. This has drawn considerable criticism from scholars and other critics proclaiming that the academic integrity of the institution is threatened, especially when scandals of academic deviance and abuse incurred by athletes and athletic administrators tarnish the images of institutions of higher education.

Regardless of these challenges, the momentum for college athletics continues to (a) supply the student body with an avenue to unite and share in a common tradition and sociocultural practice; (b) provide athletes with the opportunity to use their athletic talents in exchange for an athletic scholarship (especially at the NCAA Division I and II levels) and, for many, a college education; (c) provide athletes with the opportunity to develop transferable and marketable skills (e.g., character development, hard-work ethic, ability to work with members of a team to achieve a common goal) within the highly competitive environment of college athletics; and (d) give national and international exposure to institutions that previously have not enjoyed this privilege. Thus, the future of college athletics presents an ambiguous forecast: continual controversy and criticism at the Division I level, if athletic reform is not successful in managing the discrepancies between athletic capitalism and the educational, research, and service mission of higher education; and for the smaller divisions, college athletics will continue to provide the aforementioned services and blend the pursuit of athletic excellence with the context of higher education if these smaller institutions adhere to the model of amateurism.

ATTACHMENT

Attachment, an important component of affective development, is the affectional bond that a child has with significant others. This entry addresses what is known about the link between attachment and education and covers three main areas. First, this entry discusses children's interest in and ability to participate in relationships that promote learning, including the relationship with the primary caregiver as well as relationships with early care providers and teachers. Next, this entry discusses specific language, cognitive, and social/emotional outcomes associated with attachment. Finally, this entry addresses biological underpinnings that begin to explain why attachment may be linked with educationally relevant outcomes in young children.

Participation in Relationships That Promote Learning

In discussing early relationships, it is important to begin with an overview of key concepts of attachment theory, as applicable to educational contexts. First, for

the purpose of research, attachment relationships are classified into distinct categories based either on a laboratory separation-reunion paradigm (Strange Situation Procedure) or observation of the child and a caregiver in naturalistic context (the Attachment Q-Set), both with strictly defined scoring systems. Broadly, attachment is viewed as secure when the child responds with warmth and trust to a particular caregiver. Attachment is viewed as insecure when the child responds to a caregiver in either cool/avoidant or overly dependent/clingy ways. Because attachment relationships are considered to be unique to each child–caregiver dyad, children are thought to have the possibility for secure relationships with the different adults in their lives, particularly during infancy but also into the school years as children meet new teachers and have the possibility to enjoy trusting relationships with them, even if they did not arrive at early care or education settings with that trust in a prior caregiver. Thus, while parent–child relationships are considered to be most salient for a child's development, a child can have unique attachment relationships with different adults and, thus, unique relationships with each teacher. The security of these relationships may be different from the child's relationship with his or her parents.

For the most part, however, children have relationships with others that are similar to the relationships with their principal attachment figures at home, mainly because children form "internal working models" about relationships based on these early experiences. According to this important attachment concept, individuals use a frame of reference from which to view new experiences. Related to learning and, in particular, the academic environment, an individual's internal working models will affect the way new information and experiences are filtered, the responses an individual evokes from others, and the niches they develop for future experiences. Thus, a child enjoying a secure relationship with the mother is seen as more likely to establish secure and nonconflictual relationships with teachers. Similarly, a child enjoying a secure relationship with the mother is seen as more likely to establish secure and nondependent relationships with teachers. Thus, internal working models are thought to create templates for the quality of future relationships with other attachment figures. Although infants, school-age children, and adolescents may evoke relationships that are similar to what they have experienced, early care professionals and educators can respond to insecure children in ways that they are not accustomed to, thereby providing the opportunity for insecure children to experience secure relationships, perhaps for the first time.

Children's interest in and ability to participate in relationships is thought to be important for early learning. According to attachment theory, processes that lead children to acquire school competencies are rooted in the stability and quality of interactions in early relationships. For example, in the context of early literacy development, researchers A. G. Bus and M. H. van Ijzendoorn have found that secure attachments to primary caregivers are linked with more optimal interactions during joint book reading with that caregiver, specifically greater frequency and better quality of interaction. When securely attached dyads are reading together during the early and preschool years, they are more likely to be attentive to the reading material and to enjoy their time in this activity. The researchers concluded that securely attached children are more likely to be growing up in an environment where they become interested in literacy, because they are interested in interactions with their caregivers.

As stated earlier, an attachment relationship can form between a child and an adult other than the primary caregiver, such as an educator. Play-based child assessment of this postulate via child drawings reveals child attachment, both secure and insecure, with educators. These relationships can play a significant role in shaping both children's motivation to learn and their classroom learning experiences.

It is important to note that educators bring to their relationships with students not only their own formal training but also their personal experiences and attachment styles. Individual educator strategies for supporting learning through secure child–educator relationships include the following: understanding of socioemotional development, promotion of a supportive socioemotional climate in the classroom, attentiveness to each child, and clear and open expectations about students' academic feedback and success. These strategies have important implications for child learning outcomes, as school-age children and adolescents remember information more readily when there is a positive valence attached to the setting.

Attachment-Relevant Qualities and Child Outcomes

Research indicates that securely attached children are more likely than insecurely attached children to show

advanced levels of symbolic play. Studies have pinpointed sensitive maternal involvement (a significant predictor of attachment) as being linked with sophisticated symbolic play in toddler-age children. More specifically, both the level of play and length of time that a child engages in symbolic play are enhanced by the mother's making suggestions and communicating with the child during the child's play session.

These advantages for securely attached children in early childhood may, in part, be related to theory of mind capacity—the ability to consider another individual's perspective. Such parents often use reasoning in conversation with their children and discuss emotions. These behaviors are known to foster early social cognition in children.

Securely attached children have been found to show a greater "secure readiness to learn." Research indicates that when primary caregivers have established secure relationships with their young children, these children are more likely to be more attentive at school and to be interested in the learning environment.

Attachment also has been shown to affect expressive language outcomes, more so than cognitive outcomes. Meta-analyses have documented that securely attached children are more competent in the language domain than are their insecurely attached counterparts. Such language competencies may be linked with the relational context in which skills are developed. It is thought that language development may best be stimulated in the context of sensitive caregiver–child interactions.

Of the several different insecure attachment types, the disorganized attachment classification is noteworthy in terms of educational outcomes. Children who show this pattern are more likely to have been exposed to a difficult, unstable, and fear-evoking home environment than other insecure children, such as abuse and neglect. It is posited that the anxiety raised in task performance related to the reactions of others, for example, educators and peers, might cause dysregulated thought processes and, in turn, affect further learning. It is also suggested that difficulty with self-regulation in this group affects learning. Overall, cognitive functioning impairments in children with disorganized attachment places them at risk for academic problems.

In addition, securely attached school-age children and adolescents have better peer relationships than do insecurely attached children. Compared with other insecure or secure children, the disorganized group is likely to show more behavior problems, including aggression.

For children with learning differences, educator–child attachment is a particularly important factor in child adjustment. Secure educator–child attachment has been shown to mediate adjustment for children with learning differences. In this way, secure relationships serve as a protective factor to support learning via better child adjustment.

Some Biological Underpinnings

The brain develops in a predictable way, from the most simplistic to the most complex systems. It is generally thought that there are windows of time in which neuronal systems develop and that environmental influences during these time periods can significantly affect the developing brain by either hindering or supporting future development. The early years of a child's life are important foundational years for neurological development because environmental impacts during this period have the potential to affect later, more complex, brain development. Security of relationships has been shown to modulate arousal and attention. The majority of empirical work done to establish this relationship has been done with insecurely attached populations.

Additionally, information is stored in the brain in a use-dependent way. Thus, the more an area of the brain is activated, such as the stress response system, the more developed it becomes. Because early experiences play such a large role in shaping the stress response system, these presentations become more ingrained when, and if, children are exposed to chronic stress.

Implications

It is important for educators to see opportunities for establishing secure attachments. Rather than viewing children as having "within the child" characteristics, it is important for educators to understand that children have the capacity for different relationships, and in these different relationships, they can manifest various individual characteristics. In more mutually rewarding relationships, children have the capacity to learn more optimally, as they attach a positive valence to the school environment. Positive and secure attachments to educators and to peers at school are part and parcel of secure attachments to school. Security of

relationships not only helps children connect with school but also supports their future learning.

ATTACHMENT DISORDER

Attachment is defined as an affectional bond that ties a child to significant individuals in his or her life and endures over time. All infants raised in homes with at least one consistent parental figure grow in their emotional connection over the course of the first year of life and thus become attached. If an infant is being raised by several individuals (e.g., mother, father, grandmother, or child care professional), the infant then is in a multiple caregiving situation and will likely form an attachment with each of these important individuals, an attachment that reflects the unique quality of each of these relationships.

Although *attachment disorder* has no clear definition, it is generally defined as a failure to develop or to show a selective attachment toward at least one individual. It is thought to be caused by abuse or neglect, lack of a consistent attachment figure (as in institutional settings), or disruptions in existing relationships (as in multiple foster placements). The sensitive interactions that occur between a young child and the caregiver is thought to create a secure attachment, and

when positive interactions are lacking but there is nonetheless a consistent caregiver, an insecure attachment is thought to form. In contrast to this normative scenario, attachment disorder is the lack of the formation of a selective attachment and the impairment of the child's ability to form a focused attachment.

The *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision) (*DSM–IV–TR*) divides attachment disorder into inhibited and disinhibited subtypes and requires that the symptoms be present before the age of 5 years. Attachment disorder is referred to as reactive attachment disorder. Disinhibition includes inappropriate approach, an overfriendliness toward unfamiliar adults, and inappropriate use of physical boundaries. Inhibition refers to both a child's inability to initiate or to accept comfort and a child's general fear of and withdrawal from social contacts. Although these definitions may seem clear, recent commentaries by prominent individuals in the field indicate that there is no well-accepted assessment protocol for making the diagnosis and that investigators utilize different meanings.

Attachment Theory

John Bowlby began to formulate attachment theory (integrating numerous disciplines, including, but not limited to, cognitive science, ethology, and object relations theories), and his work was the basis for a major departure from existing psychoanalytic views, which focused more on fantasy life than on actual interactions and relationships. He focused on the role of brief, as well as long-term (temporary as well as permanent), separations of infants from their caregivers and their potential impact on defensive processes of the growing infant. A focus on childhood mourning in the event of parental loss through death was also given considerable attention in terms of children's ability to attach and love. Bowlby's work was not solely on clinical populations of patients but also on normative individuals' experiences.

In 1950, Mary Ainsworth joined Bowlby's research team and was fascinated by the terrain of research ideas offered by attachment theory. It was Ainsworth and her team who developed a laboratory-based methodology for testing Bowlby's theory—the now well-known Strange Situation Procedure. In brief, an infant and caregiver (an attachment figure) are introduced into this unfamiliar context, which involves two separations from the caregiver as well as two reunions

with the caregiver. The separations are very brief (from 30 seconds to 3 minutes, depending on the reaction and stress shown by the infant). The reunion response of the infant is thought to show the infant's view of this relationship with this particular caregiver, with happy greetings (even after potential turmoil during the separations) being indicative of a secure relationship. In contrast, avoidance, clingyness, or a mixture of such behaviors and bizarre reactions are reflective of an insecure relationship with this caregiver. While there is only one form of security, as suggested above, there are several forms of insecurity, as seen in the Strange Situation, with avoidance being referred to as insecure/avoidance, clingyness being referred to as insecure/ambivalence, and a mixture of responses including bizarre behaviors such as freezing or stilling being indicative of insecure/disorganization. It should be noted that Ainsworth and her team identified the first three, whereas Mary Main and Judith Solomon identified the disorganized pattern.

Bowlby, Ainsworth, and numerous attachment researchers since then have been fascinated by the concept of maternal sensitivity and the mounting evidence on the relation between sensitivity and a secure attachment. Attachment researchers have concluded that when a parent is sensitive to an infant's cues and communications, the infant has a greater chance of forming a secure and trusting attachment connection with that person. When a parent is inconsistent or reacts in negative and/or overly emotional ways, it is thought that the infant may begin to form an anxious, resistant form of attachment to that caregiver. Such parents may even look sensitive on occasion, termed by Zeynep Biringen as *apparent sensitivity.* When a child is constantly rebuffed and rejected by a parent, an emotionally distant relationship begins to form, termed *insecure avoidant attachment.* When a child is frightened by words or deeds, is exposed to extremes in parenting dysfunction (such as abuse), or experiences significant instability in the caregiving environment, or when the parent displays difficulties in expressing normative affect, an insecure/disorganized pattern of attachment is thought to develop. These patterns of attachment are seen in normal populations and, in many ways, are viewed as normal variants, although the secure is associated with many more positive child outcomes than are the insecure forms of attachment. Bowlby asserted, and later empirical research has corroborated, under stable life circumstances, these patterns tend to persist over time.

Although attachment theory set a firm foundation for understanding social and emotional development in infants and young children in normative settings and normative families, with the range of functioning being anywhere from secure to insecure, the theory and the research have not tackled the lack of development of a focused and selected attachment (which is the definition of attachment disorder). The reason for this lack of emphasis is that most of the research on attachment has involved a specific and focused attachment figure, who brings the infant or young child to the Strange Situation Procedure. The insecure/disorganized form of attachment comes closest to an attachment disorder. However, it should be said that not all cases of disorganized attachment involve an attachment disorder, and in fact some cases of disorganized attachment may be a transient situation for some children. Thus, there is a schism between attachment theory/research based on elegant conceptualizations and/or methodologies used to understand normative populations and the current need to better conceptualize, assess, and to research the topic of the clinical phenomenon of attachment disorder.

Behaviors Seen in Other Diagnoses

Children with attachment disorder have been described as displaying aggression, lack of impulse control, resistance to authority, manipulativeness with others, lack of conscience. Such behaviors may be seen in other disorders, such as conduct disorder, or in a comorbidity between conduct disorder and attention deficit hyperactivity disorder. The current thinking is that diagnosticians should first be sure to assess for other conditions and give the label "attachment disorder" only in the rare circumstances that it is warranted.

Treatment

There are many types of treatment designed for attachment disorder, though there is no treatment that is evidence based. Approximately 70 studies have implemented attachment-based therapies (emanating from the field of attachment research), with the primary focus being the improvement of maternal sensitivity and attachment security, as conceptualized for normative populations. Interestingly, none of these studies has been implemented on groups at-risk for an attachment disorder or those who have been diagnosed.

Holding Therapy

One treatment that has created considerable controversy is holding therapy. The theory behind holding therapy is that a child's anger and rage must be released for the child to be able to function properly in society. In addition, because such a child has not experienced an attachment and is resistant to closeness, the emotional distance needs to be confronted. Physical holding, binding, forcing touch and eye contact, pinching, knuckling, licking, and punishments regarding food and water are all part of the arsenal of techniques that are used. These efforts are used to confront the rage and anger of the child and to (hypothetically) attach the child to the care provider. Opponents of this approach (which include a substantial number of attachment and trauma researchers) describe the traumatizing nature of these treatments as well as the lack of theory or research to support such extreme interactions, some of which have caused child deaths, as rebirthing is simulated in the context of restraint.

Web sites provide information on enrolling one's child in this type of therapy (often referred to as *attachment therapy*), with additional parent training (labeled *attachment parenting*) to be conducted at home. It is important that this use of attachment parenting be differentiated from a different popular use, which supports physical and social contact to create attachments (but is not considered traumatic in any sense of the word as described here). The work on holding/rage therapies are considered by the field of attachment as unsubstantiated therapies that should not be referred to as attachment therapy.

Implications

Attachment disorder is a misunderstood diagnosis, with clear linkages to maltreatment as part of the diagnosis via the *DSM–IV–TR* (therein referred to as reactive attachment disorder) but with tenuous ties to the field of attachment research. Many state that the link with maltreatment is unfortunate because the link leads to a misdiagnosis for many maltreated children who do not meet the criteria for the diagnosis or potentially any diagnosis. Similarly, those being adopted through international adoptions also are diagnosed without sufficient evidence of the disorder.

Children should not be assumed to have the disorder just because of a particular history of maltreatment or institutional rearing. The field does not have an assessment protocol, which likely will precede the empirical research in this area. In educational and other settings, it is important for children not to be labeled with an attachment disorder just because they are adopted or just because they have experienced maltreatment or foster placements. It is the inability to form selective attachments that is the hallmark of attachment disorder. If the diagnosis is accurate, however, attachment disorder is difficult to treat, and even in the most extreme of interventions available to interventionists (which is adoption into a loving home), the child may not develop the capacity for emotional connection and attachment.

ATTENTION DEFICIT HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD) is a diverse behavioral syndrome affecting 3% to 7% of children in the United States, characterized by inattention, overactivity, and impulse control problems. This disorder, as currently understood, can manifest in one of three ways: Individuals with this disorder may be primarily inattentive, may be primarily impulsive/hyperactive, or may present with a combination of both inattention and impulsive/hyperactive behaviors. Research indicates that boys are 3 times more likely than girls to be diagnosed with this disorder and tend to demonstrate the more visible externalizing aspects of the condition, which include overactivity and behavioral dyscontrol. The disorder, which has gained increasing recognition and research over the past 3 decades, affects the educational, social, and behavioral functioning in lives of a substantial number of school-age children, a fact that has significant implications for educational programming in schools.

Research focused on the causes of ADHD has implicated genetic and neurochemical factors as playing a large part in the etiology of this disorder. It appears to be the case that, although environmental factors may play some role in how ADHD symptoms are expressed, maintained, or exacerbated, brain-based and heredity explanations appear to be more likely factors in the expression of ADHD. Although the disorder may be due to these genetic and neurobiological factors, the way in which ADHD is perceived by others is influenced by the context in which the individual is viewed. Children might tend to be viewed as less hyperactive, for example, in a physical education class in which they are required to run and be active as compared with a classroom in which sitting still and focusing on a lesson are required. Therefore, the severity of the disorder can be influenced by the lens of the observer in some cases. For those with a severe form of ADHD, this hyperactivity appears to manifest more clearly across multiple settings.

Some researchers have argued that ADHD is a misnomer for a set of behavioral symptoms resulting from problems with brain-based executive functioning. Executive functioning serves a regulatory purpose for behavior and is thought of as involving higher-order cognitive skills that allow individuals to plan, organize, direct, and control behavior. This capacity also allows individuals to select and persist in adaptive behaviors. The kinds of behaviors that individuals with ADHD have difficulty with are also the kinds of behaviors regulated by this executive system.

In addition to this overseeing function, the executive system assists individuals with time management, memory, and metacognition, or the capacity to think about one's own thought processes and strategies. It is well known that these executive skills develop over the course of our lives and assist in tasks of daily living as well as impacting upon the educational experience of the individual. In fact, research has found that individuals with ADHD may be susceptible to a kind of time blindness thought to be related to deficits in their executive functioning. Self-regulation and self-control, as assisted by skills involving response inhibition, self-regulation of affect, task initiation, and adaptability, are also often problematic for those with ADHD.

ADHD has been recognized as a distinct disorder for many years and has been known by a number of names, including minimal brain dysfunction, hyperactive child syndrome, hyperkinetic reaction of childhood, and attention deficit disorder. The current label of attention deficit hyperactivity disorder refers to one of three variants, with subclassification as primarily inattentive, primarily impulsive, or combined type. The diagnostic criteria for ADHD are outlined in the *DSM–IV*, the primary diagnostic handbook and taxonomy of mental disorders. The diagnosis requires six or more symptoms of specifically outlined symptoms of inattention, six or more symptoms of hyperactivity or impulsivity, or twelve or more symptoms for the combined type. In addition to the manifestation of these symptoms across multiple settings, the diagnosis also requires that the symptoms have been present for at least 6 months with an age of onset before the age of 7. The intensity of the disorder can be described as mild, moderate, or severe. Typically, ADHD is first diagnosed when the demands of the environment make the symptoms most noticeable, which is usually when a child reaches school age. The disorder can manifest itself at younger ages, as well as with more severe forms of the disorder likely identified at earlier ages.

ADHD can be diagnosed by a number of different types of professionals, including psychologists, developmental pediatricians, psychiatrists, and clinical social workers. Each professional will bring different types of understanding to the diagnosis and treatment of the disorder; assessment tools that will assist in the

formulation of a diagnosis also vary according to the clinician's expertise. For example, a pediatrician may feel comfortable with making recommendations for medical and for psychopharmaceutical interventions but may request a more in-depth evaluation of cognitive ability or social emotional functioning that would include a comparison of the referred child's behavior to other children with and without the disorder. In this case, for example, a referral to a school or clinical psychologist might be made for evaluation that would involve normative comparisons.

Although the symptoms of ADHD may seem very familiar to many individuals in a fast-paced, complex culture, and most people feel inattentive, fidgety, or impulsive at different times, it is not the case that we all have ADHD. The diagnosis of the disorder is made as a function of the degree or severity of the symptoms and the extent to which the symptoms have an impact on the person's daily functioning. So, while the nature of the disorder is such that we may all have *some* of the characteristics of ADHD, the actual diagnosis is made based on a variety of variables as well as historical and developmental factors that have a significant impact on the individual's functioning and may range from very mild to very severe. The kinds of information required for such a diagnosis of ADHD are likely to involve interview, a review of the individual's medical and psychiatric history, observations, and rating scales. The diagnostic process should involve the collection of relevant data across multiple settings, multiple sources, and/or multiple informants. Broadband and narrowband behavioral rating scales may be used toward this end. Broadband rating scales assess a broad range of behaviors that might be associated with many types of disorders. Narrowband rating scales target, more specifically, the types of behaviors associated with ADHD. Other formal psychological tests may also be useful in pinpointing an individual's strengths and weaknesses.

Because the age of onset of ADHD is before or within the typical school age, many students with ADHD experience academic difficulties. Inattention can interfere with the acquisition of new knowledge in school and with the retention of already learned concepts. Disruptive behaviors can also interfere with learning and create secondary social or interpersonal problems for students. The research indicates that children diagnosed with ADHD are at greater-than-average risk for experiencing a range of academic difficulties, relationship problems, and conduct problems because of their difficulties with sustained attention

and behavioral disinhibition. Boys are more likely to be diagnosed with this disorder because of the disruptive behaviors they demonstrated within the classroom setting. Inattention, the primary symptom of ADHD in girls, is oftentimes less likely to catch the eye of teachers and caregivers than the disruptive or impulse control problems associated with the clinical presentation of boys.

In addition to academic challenges, the problems that individuals with ADHD experience can change over time due to development. As children grow, increasing behavioral competencies or skills emerge that may affect the presentation of symptoms. In a positive view, for example, increasing capacity to reflect on their own thinking (metacognition), which occurs over the years of child development, may assist the impulsive child in developing effective learning strategies. As teenagers get older, they may expect to engage in increasingly complex psychomotor tasks such as driving—an important rite of passage for many teens. However, adolescent and young adults with ADHD appear to have more automobile accidents and problems with speeding, resulting in more traffic violations and suspended licenses than typical peers, creating additional potential problems associated with these changes in development.

Once a diagnosis of ADHD is made, intervention is often needed to manage the behavioral and cognitive symptoms of the disorder. The most common treatments for ADHD include the use of psychostimulant medications, behavioral programming, psychosocial interventions, and parent training. Psychostimulant medications have been used for many years to treat children with behavioral disorders. In fact, the first use of stimulants in the United States was at the Emma Pendleton Bradley Home for Children in Rhode Island in 1937. The stimulants traditionally used to treat ADHD have included medications such as Ritalin and Dexedrine and are the best researched of any medication for childhood behavioral disorders. A more recent development in the psychopharmaceutical treatment of ADHD is the development of a norepinephrine reuptake inhibitor atomoxetine (Strattera), which appears to hold promise in the treatment of ADHD and holds little risk for abuse and other negative side effects.

Behavioral programming is a form of treatment of the symptoms of ADHD that is based on the principles of applied behavioral analysis and operant conditioning. In this form of treatment, a student's behaviors are viewed in the context of antecedents and consequences

that increase or decrease the likelihood that a particular behavior will be repeated. These antecedent, or consequence, conditions are then experimentally altered to determine what conditions are perpetuating the behaviors. A behavioral management plan is then created for implementation with the student either at home or at school. The plan might include altering the environment in specific ways, such as posting rules so that the student is reminded about behavioral expectations, or moving the student to a place in the classroom that is likely to allow for visual contact with the teacher, for example.

Research indicates that when behavioral approaches are intensive and administered with consistency and in the way in which they were designed, significant improvements can be made in some of the symptoms of ADHD. There also appear some promising results with the use of self-monitoring techniques for the management of symptoms of ADHD. Self-monitoring techniques involve the application of operant behavioral principles with the monitoring of progress to be done by the client or student.

A number of studies have been conducted to evaluate the effectiveness of medical versus behavioral treatments of ADHD. A recent, large, and well-regarded study indicates that when comparing medication management and behavioral interventions, either medication management alone or a combined medication/behavioral approach appears to be most effective. In fact, in terms of academic performance, anxiety, oppositionality, parent–child relationships, and social skills, these combination approaches appear to be most effective.

Other research has examined the effects of psychosocial interventions and parent training on the symptoms of children with ADHD. Improving knowledge about the disorder and clarifying myths about treatment and prognosis are major goals in psychosocial interventions. Because students with ADHD might have associated problems with relationships as a result of their impulsivity, teaching social skills and conflict resolution strategies may be an important element in psychosocial training. Training parents in the treatment of ADHD, using communication and problem-solving skills, as well as behavioral management principles, also appears to be a significantly effective intervention as well.

There are a number of myths about ADHD that are worth noting. Some people believe that people with ADHD are not able to "pay attention," as its name suggests. This, however, is one of the reasons for the inadequacy of the diagnostic label. Individuals with ADHD may have difficulties with sustained attention but are not attention-less as the name implies. ADHD is also not a disorder related to what we traditionally think of as intelligence. Many very bright, capable, and productive individuals struggle with this disorder. In terms of treatment myths, some people are concerned about using "drugs" to treat this behavioral syndrome with the very genuine concern that medication will set precedence for future or illegal drug-taking behavior. In fact, research indicates that individuals who are properly treated for ADHD with safe and effective medications are less likely to abuse drugs and alcohol. Although intuitively appealing, diet and nutritional interventions have failed to show a long-term or significant impact on the treatment of ADHD.

In the past, ADHD was assumed to ameliorate into adolescence. We now know that the symptoms of the disorder often persist well into adulthood. Epidemiological studies report rates of persistence of the disorder from 33% to 66%. Adults with ADHD can continue to experience functional impairments due to their symptoms and may continue to require treatment over the course of their adult lives. Although some of the executive skills involved in planning and organization that are deficient in individuals with ADHD will emerge and develop over time, it seems to be the case that these individuals continue to struggle with ADHD-like behaviors that can affect their daily lives and careers. For this reason, identification of the disorder and early intervention or treatment are important in minimizing the long-term impact of the symptoms of this disorder over the life span.

AUTISM SPECTRUM DISORDERS

Autism, autism spectrum disorders (ASDs), and related pervasive developmental disabilities are neurological disorders that involve primarily problems of communication, socialization, and behavior. These terms are commonly used to describe the same disabilities; hence, the term *ASD* will be used hereafter. Individuals diagnosed with ASD express the disability in a variety of ways, and a wide range of abilities, strengths, and limitations are common. This once very rare condition of childhood is now commonly diagnosed. ASD has been one of the most researched conditions over the past few decades, and much progress has been made in understanding and supporting persons with the disability. The exact causes are not fully understood, although poor parenting has been thoroughly disproven as a cause.

Even when compared with other disabilities, ASD is an enigma. Children and youth identified as having ASD present highly individualized characteristics that set them apart from their typically developing peers and their peers with other types of disabilities. Some individuals with ASD have near- or above-average cognitive and language abilities with evidence of their disability manifested in the form of subtle social peculiarities. Others have significant cognitive impairments, limited or no expressive language, and severe behavioral and social abnormalities. Individuals with ASD sometimes demonstrate isolated abilities and highly developed splinter skills that contribute to the syndrome's mystery. Fierce debates over the causes of ASD, intervention choices, and educational programming have also been prominent in the recent history of the disability.

Nature and History of Autism Spectrum Disorders

One can logically speculate that ASDs have existed for centuries. Old tales and legends of children and adults with characteristics similar to today's ASDs are scattered throughout history. Stories of the "Holy Fools" of Russia, odd monks, mysterious-acting children, and other individuals who possibly had autism or a related condition can be found in several textbooks. The amount of historical information on ASD is limited for a number of reasons: Families may have kept individuals with ASD from contact with the public; those with mild disabilities may have been perceived to be peculiar, albeit not disabled; some individuals who exhibited bizarre behavior might have been considered possessed or under the influence of magic or spells; some persons with disabilities might have been left to perish in the wild or killed; and medical conditions associated with ASD (e.g., seizures) would have likely resulted in the early death for some.

The words *autism* and *autistic* come from the root Greek word *autos* meaning "self." In this connection the word *autism* was probably first used in the early 1900s by Swiss psychologist Eugene Blueler to describe children who had schizophrenic symptomology and had difficulties relating to others. Major recognition for identifying modern-day notions of ASD is credited to Leo Kanner. In his 1943 seminal work, Kanner described a unique group of children whose behavioral anomalies made them qualitatively different from other children with identified disabilities; he used the term *autistic* to describe them. According to Kanner, these children manifested similar abnormalities from infancy or early childhood, including (a) an inability to relate normally to other people and situations; (b) delayed speech and language development, failure to use developed language for communication purposes, and/or other speech and language irregularities such as echolalia, pronoun reversal and misusage, and extreme literalness; (c) normal physical growth and development; (d) an obsessive insistence on environmental sameness; (e) an extreme fascination and preoccupation with objects; and (f) stereotypic, repetitive, and other self-stimulatory responses. The characteristics of autism as first described by Kanner over half a century ago have been revised, refined, and broadened in recent years, yet current definitions and conceptualizations of ASD continue to reflect many of his original observations.

Working in the same era as Kanner, Viennese medical student Hans Asperger, in 1944, worked with a group of boys whom he described as having an "autistic psychopathology/personality." The children Asperger worked with not only had similarities to Kanner's children but also manifested major differences, such as not having clinically significant

cognitive delay. Because of the language barrier and World War II, Asperger's work was not translated into English until 1981.

Although Kanner referred to genetics and biology early on in his work, he and others soon speculated that the cause of autism was poor parenting and breakdowns in the emotional bonds between parent and child. Bruno Bettelheim, working at the University of Chicago, spoke and wrote about the "refrigerator mother" and emotional difficulties of the parents that led to children having autism.

Perspectives on autism would change in the early 1960s. Bernard Rimland, a researcher and parent of a child with autism, challenged the notion that autism was caused by poor parenting and instead advanced that the disability's etiology was biological and genetic. By the mid-1970s, the acceptance of a psychogenic cause for autism was being discounted, and the neurological nature of the disability was widely accepted.

Andreas Rett made a discovery in 1966 that would eventually add a condition to the autism classification. Rett observed several girls in his practice who had characteristics similar to autism, albeit with significant differences. This new disability would ultimately be named after him—Rett's disorder.

In 1980 autism was added to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (Third Edition) *(DSM–III)*, replacing the category of early infantile autism. By 1987 another diagnostic label, pervasive developmental disorder–not otherwise specified (PDD–NOS) was added to the *DSM–III*. PDD–NOS was added to the continuum as a means of diagnosing individuals who had some characteristics or more mild traits of autism but not enough symptomology for a full diagnosis of autism. In the mid-1990s childhood disintegrative disorder, Rett's disorder, and Asperger's disorder were added to the *DSM* (1994). Autism was now officially described as a spectrum of similar neurological disorders.

ASD has been one of the most researched conditions over the past three decades, and much progress has been made in understanding and educating students with the disorder. Although poor parenting has been thoroughly disproven as a cause of autism, the exact causes are not fully understood. There are many theories to explain autism, including biological, psychological, cognitive, and affective. Some models are purely genetic and biological in nature, whereas others include environmental causation or a combination of factors.

Definitions and Conceptualizations of Autism and Autism Spectrum Disorders

Commonly used definitions of ASD include those of the American Psychiatric Association (i.e., *DSM*) and the definition advanced by the Autism Society of America. These and other definitions of autism are discussed.

American Psychiatric Association

The most widely used definition of autism in the United States is that advanced in the most recent version of the *DSM* (*DSM–IV–TR*), published in 2000 by the American Psychiatric Association. The *DSM* is an extensively used clinical practice guide; it classifies autism as a pervasive developmental disorder (PDD). In this context, children and youth identified as having a PDD manifest severe and pervasive disabilities in several areas of development, including social interaction reciprocal skills, communication, or narrowly defined and unusual and stereotyped behavior and interests. Such behavioral patterns are demonstrated in the first few years of life and are clearly abnormal relative to a given child's mental age or developmental level.

Subcategories of PDD include autistic disorder, childhood disintegrative disorder, Rett's disorder, Asperger's disorder, and pervasive developmental disorder–not otherwise specified (PDD–NOS).

Autistic Disorder—(Autism)

Autistic disorder, per *DSM–IV–TR* guidelines, is reserved for individuals who display social interaction impairments, communication impairments, and repetitive, stereotypic, and restricted interests and activities prior to 36 months of age. In the majority of cases, children diagnosed as having autism have some degree of cognitive impairment.

Childhood Disintegrative Disorder

In accordance with *DSM–IV–TR* diagnostic standards, children identified as having childhood disintegrative disorder (CDD) typically have behavior patterns similar to those of children with autism. That is, they display the same qualitative social interaction, communication, and behavior/interests impairments as children with autism. However, they differ from children with autism in age of onset of the disability. Children diagnosed with autistic disorder must display

symptoms of PDD before they reach 3 years of age. In contrast, children with CDD experience a period of normal growth and development prior to manifesting social interaction, communication, and behavioral impairments. Thus, following at least 2 years of apparently normal development (but before 10 years of age), children diagnosed as having CDD display a significant loss of skills they previously had acquired. Skill loss falls in at least two of the following fields: language (either expressive or receptive), social skills and social interaction ability, adaptive behavior, bowel or bladder control, play skills and interests, or motor skills. Prognosis for children identified as having CDD is guarded, and typically the social, language, and behavioral challenges associated with childhood disintegrative disorder remain throughout the life span.

Rett's Disorder

Rett's disorder, also called Rett's syndrome, was added to the PDD category of the *DSM–IV* in 1994. In 1999, the gene (MeCP2) that causes 80% of the cases of Rett's disorder was identified. Although Rett's disorder almost exclusively occurs in females, there have been recorded cases of males with this disability. With onset typically occurring by age 1 to 2 years, those diagnosed with Rett's disorder usually develop in an apparently typical fashion during the first five months of life. Onset of the disability is characterized by head growth deceleration; loss of previously acquired motor skills, including purposeful hand movements; stereotypic hand wringing or hand washing; various motor impairments; and social and communication impairments. Loss of these skills is typically progressive and permanent, and prognosis is poor.

Asperger's Disorder

In accordance with *DSM–IV–TR* diagnostic criteria, the essential feature of Asperger's disorder is impaired social interaction. As described earlier, Hans Asperger identified a group of higher-functioning children with autistic-like symptoms in 1944, but this work was largely ignored in the United States until the 1980s. Subsequent to a translation of Asperger's work into English, the syndrome began receiving significantly more attention. This renewed interest has been stimulated, at least in part, by the expansion of the conceptualization of ASD to include individuals with autism-type symptoms who are able to function at a relatively high level. Researchers and practitioners have observed that children with Asperger's disorder are usually able to speak fluently by the time they enter school, albeit their initial language development is sometimes reported to be slow. In spite of their speaking fluency, individuals with Asperger's disorder are noted for having an odd communication style. Many individuals with Asperger's disorder are also reported to be very interested in other people. However, in spite of this interest, they tend to be socially awkward and socially unskilled throughout their lives. Although the exact prevalence of Asperger's disorder is unknown, it appears to be a relatively common form of ASD.

As with other subtypes of ASD, significant elements of the *DSM* diagnostic criteria for Asperger's disorder fall in the areas of *social interaction impairment* (e.g., eye contact difficulties, difficulty in recognizing and reading facial expressions and body language, inability to develop and maintain peer relationships, difficulty in relating and interacting with others) and *stereotypical and restricted patterns of interest and behavior* (e.g., limited, stereotypical, and abnormal interest patterns and aberrant and stereotypical movements, such as flapping). *DSM* diagnostic criteria for Asperger's disorder also include an absence of language, self-help and cognitive delays, a lack of environmental curiosity, and significant occupational and/or social impairment.

Pervasive Developmental Disorder–Not Otherwise Specified

The fifth subtype of pervasive developmental disorder identified in the *DSM–IV–TR* is pervasive developmental disorder–not otherwise specified (PDD–NOS). This somewhat vaguely defined terminology refers to children who evidence significant and pervasive problems in developing reciprocal social interaction skills, verbal or nonverbal communication skill deficits and problems, and/or stereotyped behaviors and interests. The diagnosis of PDD–NOS is used when the criteria for other forms of ASD or other disabilities are not met.

Autism Society of America Definition of Autism

The Autism Society of America (2006) has a widely used definition of autism that is closely aligned with both the criteria used in the *DSM* and Kanner's original work. It also reflects the modern view of autism as a spectrum of neurological disorders. The Autism

Society of America conceptualization includes elements that identify autism as a neurological disorder that affects an individual's capacity to interact and communicate with others. It also identifies autism as a spectrum of disorders that often occur along with other disabilities and that affect individuals differently and to varying degrees of severity.

Other definitions of autism and other related pervasive developmental disabilities include those given by the World Health Organization, the U.S. Department of Education, and advocacy groups such as the Autism National Committee. All of these emphasize the importance of social and language deficits and behavioral anomalies, as well as the acquiring of these characteristics before age 3.

Additional Information and Issues Related to Autism Spectrum Disorders

Prevalence

Estimating the number of children and youth with ASD is difficult. This challenge is due, in part, to difficulties inherent in diagnosing individuals with ASD. There is currently no single reliable and valid test to confirm ASD; rather, diagnosis is made through use of behavioral observations along with tests, interviews, and related methods. Because these methods often rely on subjective interpretations of information and data and clinical judgment, there are differences of opinion among diagnostic professionals in their judgments of individuals who may be considered for a diagnosis of ASD.

Prevalence rates of ASD have changed considerably over the past 30 years. In 1966 it was estimated that autism occurred approximately 4 to 5 times per 10,000 births, and this figure was used through the 1980s. Current conservative estimates are now at about 30 per 10,000; more liberal projections are at about 60 per 10,000. The Centers for Disease Control and Prevention in 2006 noted ASD prevalence at 1 in 166.

Evaluations of school population data of students receiving services under the ASD label also reveal an increasing trend. From the 1991–1992 school year to the 1999–2000 school year, the U.S. Department of Education estimated that there was a 1,108% increase in those receiving services under the autism label in the United States. The exact prevalence of ASD is unknown, yet the fact is that there are significant numbers of children being diagnosed today, and therefore,

appropriate early intervention and continuing services, support, and care are of obvious critical need.

Gender Issues in Prevalence

ASD has consistently been found to be more common among males than females. Most long-standing gender comparisons have suggested that males with autism outnumber females at a ratio of 3:1 to 5:1. Asperger's disorder is also significantly more common among males. Some researchers have even posited that autism may be an extreme variant of the "systemizing" male brain, and thus this would be explanatory of the unequal gender ratio.

Explaining the Prevalence Increases

For both identified and unknown reasons, prevalence rates for autism are now much higher than in previous decades. Numerous explanations have been offered for this increase. First, the conceptualization of autism as a spectrum of disorders as opposed to just one condition has expanded the numbers of individuals diagnosed with ASD. Since the 1980s there have been four additions to the *DSM*'s PDD umbrella category. Most importantly was the addition of those with ASD who are higher functioning and who are rather different from traditional clinical and historical descriptions of persons with autism. Second, over the past 20 years there has been an enormous increase in research and popular press on ASD. As more is known about the condition, increasingly more parents and professionals notice the differences in development and behavior of children and bring these observations to those who can then diagnose ASD-related disorders. Furthermore, the Individuals with Disabilities Education Act in 1991 created a new diagnostic category for students to receive services under the label of autism. Children who had been receiving services under other categorical labels are now receiving special education and related services under the autism label. Finally, there has been much speculation about several other possible reasons for the increase in autism rates. This includes environmental exposures and toxins such as mercury. Some researchers, practitioners, parents, and advocacy groups have claimed that exposure to various toxins, such as mercury (in the preservative thimerosal), lead, aluminum, and other metals, could inhibit neural pathways and thus possibly increase the risks of developing disorders such as

autism. In February 2005, a resolution was introduced in the U.S. House of Representatives that promoted mercury-free childhood vaccinations. However, as of early 2005, many medical professionals and the Centers for Disease Control and Prevention were advising parents to continue vaccinations of children, and little sound, empirical scientific evidence had been presented to challenge these recommendations. The reasons for the significant increase in ASD are not completely clear at this time. However, it appears that the increase can be attributed, at least in part, to an increased awareness of autism among parents and professionals and the broadening of the *DSM* conceptualization of PDD.

Predisposing Factors

Autism and ASD have been shown to be associated with a number of conditions, such as maternal rubella (particularly when deafness or blindness is present), phenylketonuria, encephalitis, meningitis, fragile X syndrome, and tuberous sclerosis. Seizures are also common among some groups of individuals with autism. Depending on the strictness of definitions and the system used to classify, associated medical conditions have been estimated to co-occur with autism at a rate of 10% to 37%. As noted earlier, previous assertions that certain familial and parental interpersonal factors influence the development of ASD have been disproved.

Genetics

Although parenting styles or abilities do not cause ASD, research does support a genetic component. Studies of families with those with ASD have shown the following: (a) Much higher rates of autism occur in identical twins compared with fraternal twins; (b) a family member of a person with an ASD has a higher chance of developing an ASD than does the typical population; and (c) some autism disorders can be directly linked to a genetically linked condition, such as fragile X syndrome or tuberous sclerosis.

Medical Factors Associated With Autism Spectrum Disorders

Children identified as having ASD vary widely in terms of their health and medical characteristics. In 1943 Leo Kanner described children with autism as exceptionally attractive and healthy, and indeed, a number of individuals with autism fit this description. However, there are also children with ASD who have various medical conditions. One such common condition is seizure disorder, which often develops during adolescence. This problem appears to be most prevalent among person with measured intelligence (IQ) below 50 and among children and youth with a diagnosis of autism, CDD, or Rett's disorder. Children with greater cognitive ability and those with a diagnosis of PDD–NOS or Asperger's disorder have a much less chance of having a seizure disorder. The use of medication is widely used to ameliorate seizures as well as behavioral symptoms associated with autism, including self-injury, self-stimulatory behaviors, aggression, and attention problems.

Prognosis

In 1980, the American Psychiatric Association estimated that approximately 1 child in 6 identified as having autism could be expected to achieve marginal social adjustment, be engaged in competitive employment, and could live independently as an adult. The same group estimated that another 1 in 6 could be expected to make only minimal adjustment, and two thirds could be expected to remain severely impaired and unable to live independently. More recent assessments of prognosis suggest that early intervention in combination with a coordinated educational program bodes well for the long-term outlook for individuals with ASD.

The long-term prognosis for individuals with ASD is difficult to determine because of the diverse symptoms related to the disorder and the variance in each individual's abilities as well as their external support systems. As noted previously, even though the ASD condition is considered to be a lifelong disability, some children and youth with ASD become independent adults who show only minimal signs of the major characteristics of their disability. However, even among higher-functioning persons, the social awkwardness or difficulties usually associated with ASD will likely persist. Generally, intelligence (IQ) and language skills are most directly associated with long-term prognosis. It is important to note that these outcome predictors are more reliable when used to assess the outcome of persons with ASD as a group rather than as individuals.

Interventions and Treatments for Children and Youth With Autism Spectrum Disorders

Fierce debates over intervention and treatment choices and educational programming features have been consistent elements in the recent history of ASD. Many parents and professionals perceive ASD to be such a unique disability that they recommend that teachers use specialized and exclusively ASD-oriented intervention, methods, curricula, and programs. Books, magazines, newspapers, and television programs routinely have reports that promote the ever-increasing education and intervention choices for students with ASD.

Professionals and parents have had a particularly difficult time identifying and using the most effective methods from seemingly endless intervention and treatment choices. There is strident debate over which methods bode best for individuals with ASD, and there is often a paucity of scientific evidence to guide choices in this important area. The ASD field is well known for using, and considering use of, interventions and treatments that lack scientific support. A number of professionals and parents have pointed out that the allure of interventions and treatments that lack scientific support is understandable. That is, these methods frequently promise hope for positively responding to a lifelong disability that lacks not only a clear etiology but also a clearly effective treatment plan. Accordingly, it is understandable that professionals and parents who are given opportunities to use methods and treatments that promise dramatic improvements, even if the approach being considered lacks scientific validation, may be willing to "take a chance" and consider using techniques and strategies that lack scientific validation. Unfortunately, these methods have all too frequently been found to be ineffective.

In spite of lack of agreement on specific effective practices, there is nevertheless widespread general recognition of the need for consistent and appropriate use of scientifically supported methods. There is also a growing body of evidence on which intervention and treatment methods have the best records. These strategies and tactics are not universally used, and they can be expected to confer significant benefit only when properly tailored to fit individual student needs and when applied consistently and systematically with fidelity by well-trained and knowledgeable personnel. Currently there is strong agreement among professionals and parents that identifying and using effective practices with children and youth diagnosed with ASD are paramount. Thus, the current issue is not one that revolves around the relative importance of effective practice use but rather on identifying those methods and techniques that have effective qualities and properties.

The task of choosing and using the most effective treatment and intervention methods with children and youth with ASD is frequently complex and challenging. There does not appear to be a single best-suited and universally effective method or program for all learners with ASD. However, it is clear that there are effective methods that can be used to form the foundation of programs for students with ASD and that there are methods and strategies that are generally associated with desired outcomes. The best programs for students with ASD appear to be those that integrate a variety of objectively verified practices and that are designed to address and support the needs of individual children and youth with ASD.

Aversive Stimuli

Aversive stimuli can be defined as any cues or events that produce negative emotional feelings or a negative outcome. Any stimulus can potentially be considered aversive, because it is the production of the undesirable feeling associated with the stimulus that determines whether it is aversive or not. In general terms, the aversive stimulus most often attenuates or eliminates behavior that is paired with that aversive stimulus. As such, aversive stimuli are importantly related to various principles of learning and have major implications for a number of basic and applied research and therapeutic settings.

Aversive stimuli are a key element to escape learning (i.e., the type of learning that is based on negative reinforcement). For instance, animals can learn to escape electric footshock by pressing a bar or moving to a different part of their environment. Aversive experiences are also very important for human learning. The human nervous system has evolved so that even newborns are prepared to find certain types of sensory experiences aversive, so that those aversive stimuli will be avoided thereafter. A wealth of research data indicate that any number of additional stimuli that precede the aversive stimulus can, themselves, become conditioned aversive stimuli. The presentation of the conditioned aversive stimulus can cause a number of behavioral responses that reflect avoidance of, or escape from, the conditioned stimulus. A response that prevents the occurrence of an aversive stimulus, because of the presence of a conditioned aversive stimulus, is called *avoidance conditioning.* Avoidance learning generally occurs after escape learning has occurred, such that the response is eventually made before the aversive stimulus is encountered, so that the aversive stimulus will be entirely avoided. The relationship between escape and avoidance learning is highlighted in the two-stage theory of learning: The first stage involves classical conditioning of fear, and the second stage involves operant conditioning and the reduction of fear by avoidance responding. The negative emotional reaction to aversive stimuli is caused by the activation of parts of the limbic system of the brain, including the amygdala, hypothalamus, and anterior cingulate cortex.

In many instances, an aversive stimulus is the same as a punishing stimulus. Indeed, the use of an aversive stimulus is, in many instances, synonymous with punishment. Unlike positive and negative reinforcement, which act to increase the likelihood of a response, punishment acts to reduce the likelihood of a response, or behavior, occurring again. In other words, punishment produces the opposite outcome to reinforcement. In both experiments and applied settings, punishment may well suppress unwanted behavior—but usually only temporarily and only in situations or circumstances in which the punishment seems unavoidable. Punishment can also lead to additional behavioral issues, such as increased aggressiveness or other exaggerated emotional behavior.

Aversive stimuli potentiate certain types of learning in virtually all animals, as demonstrated by the unique ability of noxious (aversive) sensations to cause long-lasting and often permanent avoidance of the related stimuli. The Garcia Effect is the avoidance of a novel food item that has been associated with illness after only a single exposure. This type of one-trial learning enables the organism to learn the consequences of consuming that food and thus avoid poisonous food sources in the future. In recent years researchers have probed the central nervous system mechanisms that produce the aversiveness of noxious stimuli. Use of the escape/avoidance methodology uniquely facilitates an assessment of the aversive nature of noxious sensory events. Damage to limbic system structures, such as the anterior cingulate cortex, has thus been shown behaviorally to decrease the noxiousness of aversive stimuli.

Aversive stimuli are used clinically in a type of behavioral therapy called *aversion therapy.* This approach is based on classical (or Pavlovian) conditioning, so that the undesirable behaviors are paired with stimuli that produce undesirable feelings or outcomes. The goal is to attenuate or eliminate undesirable behavior. For instance, in the treatment of alcoholism, the undesirable behavior of alcohol consumption can be paired with a drug called Antabuse, also known by the generic name disulfiram. Disulfiram in the presence of alcohol produces a number of aversive physical sensations, including flushing, sweating, soreness in the head and neck, nausea, and vomiting. Theoretically, the repeated pairing of alcohol consumption with these aversive sensations will decrease alcohol consumption. However, the use of this and other

types of pharmacological aversive stimuli that cause uncomfortable consequences are typically associated with poor compliance. It should be noted that behavioral modification techniques utilizing aversive stimuli are often misunderstood. For instance, many times the same aversive stimulus is associated with either negative reinforcement or punishment. In negative reinforcement, the aversive stimulus precedes the undesirable behavior, whereas in punishment, the aversive stimulus follows the undesirable behavior. In combination with adequate cognitive-behavioral therapy, the use of aversive stimuli to treat substance abuse and other disorders may have utility, but there remains controversy as to the ultimate effectiveness of such an approach.

BEHAVIOR DISORDERS

Behavior disorder is a general term used to describe a consistent pattern of abnormal conduct impairing a child's ability to function effectively in one or more facets of his or her life. Abnormal conduct may include typical behaviors observed at a developmentally atypical rate or behaviors that are relatively uncommon or bizarre. Careful, multimodal, multi-informant evaluation by a professional is warranted to determine the presence of a behavior disorder. In this determination, a child's conduct is evaluated as to whether or not it deviates from the norm.

One standard that helps establish what is considered normal is whether or not the behavior is developmentally appropriate (i.e., typical for a child of that particular age). For instance, it would be developmentally within limits for a 6-year-old child to have difficulty staying in his seat if a teacher chose to lecture for 20 minutes. A 16-year-old, however, generally should be able to perform this task with minimal difficulty.

Another standard used to characterize behavior as disordered is whether or not the behavior defies social or cultural norms. For example, a child is expected to run around at recess or in gym class. Conversely, it is not acceptable for a child to run around during math class. Some behaviors may be considered inappropriate regardless of context, such as yelling at a teacher or principal. In establishing what is considered normal, professionals should be aware and respectful of cultural influences on behavior. For instance, a young man repeatedly refusing teacher's requests to remove his hat during class may be considered to be defiant. However, if the young man is Jewish and is refusing to remove a yarmulke, his behavior becomes understandable because the teacher's request would conflict with the individual's cultural values.

Aside from being considered aberrant, behavior disorders must also cause the child distress or impairment in at least one area of functioning, such as school, home, or social relationships. For instance, it is atypical for a young child to be able to play *Beethoven's Fifth Symphony* on the piano. Despite this behavioral abnormality, this child would certainly not be considered as having a behavior disorder, because his tendency to execute this action does not affect his ability to function at school or at home. Second, assuming the child is not continuously compelled to play the piece, it probably will not cause him much distress. It is especially important to identify behavior disorders when impaired functioning places a child at risk for harm or loss of freedom (i.e., incarceration). Examples of this are a child who bangs his head when frustrated or an adolescent who compulsively steals. Early identification of these behaviors allows professionals the time to implement steps necessary to better ensure the child's safety and maintenance in the community.

A variety of methods are available to identify behavior disorders. Typically, an adult, such as a parent or teacher, brings the behavior to the attention of a professional. The professional then uses a variety of measures and the reports of multiple informants to assess the child. These measures should include interviews, questionnaires, and direct observation. The technique of using a number of informants and assessment methods allows the professional to be more accurate in his or her determination by ruling out miscalculations such as those due to reporter biases and environmental causes of behavior. To the extent that the child is further classified, to guide service implementation, depends on the context in which the child is being treated.

Within a therapeutic context, if warranted, a child may receive at least one of a variety of diagnoses from the *Diagnostic and Statistical Manual, Fourth Edition, Text Revision* (*DSM–IV–TR*). Behavior disorder in this circumstance encompasses any of the childhood diagnoses that include a high incidence of deleterious behaviors or psychological symptoms, such as anxiety disorders, attention deficit hyperactivity disorder (ADHD), disruptive behavior disorders (e.g., conduct disorder, oppositional defiant disorder), mood disorders (e.g., dysthymic disorder, major depressive disorder, bipolar disorder), or developmental disorders (e.g., Asperger's disorder, autism). Many medical conditions, such as various neurological disorders, may also have behavioral symptoms that place youth in the behavior disorder category. Additionally, a child may not have a behavior disorder, per se, but may exhibit externalizing behaviors as a result of persistent frustration in experiencing symptoms of another diagnosis, such as a learning disorder.

Within school settings, behavior disorders are determined when a child's behavior is having a negative impact on his or her functioning within this environment. In the instance that these behaviors are so severe that additional services are deemed appropriate, the child may be found eligible for a 504 Plan or, in instances of greater impairment, an Individualized Education Program (IEP). Under current special education legislation, some psychological and medical diagnoses are categorized under labels that match the educational exceptionalities (e.g., autism, traumatic brain injury, mental retardation). Most diagnoses that are considered behavior disorders, however, fall under the special education label *emotional disturbance* (ED). Using the *DSM–IV–TR* terminology mentioned in the previous paragraph, ED typically includes anxiety disorders, disruptive behavior disorders, mood disorders, and some developmental disorders (e.g., Asperger's disorder). Alternatively, ADHD and some lower-incidence diagnoses are classified under the special education label *other health impairment.*

Common outpatient clinic approaches to intervening with behavior disorders include therapy focusing on coping skills or interpersonal problem solving and family therapy addressing communication or providing structure and consequences for the child. Within educational settings, informal and formal (e.g., 504 Plan, IEP) supports include reinforcement for desired behaviors, response-cost behavioral systems, meaningful consequences for disruptive behaviors, small-group social skills instruction and practice, and specialized settings that promote coping skills.

BEHAVIOR MODIFICATION

Behavior modification is a technique used for altering an individual's behavior and is based on the principles of learning theory. Using this technique, a behavior can be modified with respect to its frequency, duration, or intensity. Behavior modification is a comprehensive approach that can be applied to behaviors that occur too often (e.g., behavioral excesses), too infrequently (e.g., behavioral deficits), and with behaviors that are both observable (e.g., overt) and those that are not directly evident (e.g., covert). Interventions using behavior modification have produced positive results when delivered to individuals diagnosed with anxiety disorders, attention deficit hyperactivity disorder (ADHD), behavioral and emotional disabilities, and developmental disabilities.

Foundations of Behavior Modification

Classical and Operant Conditioning

Classical conditioning also referred to as *respondent* or *Pavlovian conditioning*, modifies the occurrence of a behavior by pairing two stimuli together to produce a similar response to both. In the famous example, Ivan Pavlov paired an unconditioned stimulus (e.g., meat powder that cued salivation in a dog) with a neutral stimulus (e.g., a bell, which normally would not stimulate salivation). Eventually, the bell became a conditioned stimulus once the dog learned to salivate solely by the sound of the bell.

The theory of operant conditioning, originally put forth by B. F. Skinner, offers a different method for modifying behavior. In contrast to classical conditioning, which focuses on reflexive or involuntary behaviors, operant conditioning modifies voluntary or learned behaviors. Operant conditioning emphasizes *antecedents* (e.g., events that occur prior to behavior) and *consequences* (e.g., events that occur after the behavior), both of which affect the probability that a certain behavior will occur. Whereas antecedents provide a cue for a behavior to occur, behavior is believed to be governed primarily by the consequence of the behavior. That is, the probability of a behavior taking place in the future is determined by what happens after the behavior has occurred. If the consequence of a behavior is desired by the individual, then he or she is more likely to perform the behavior in the future. If the consequence is undesired, then it is less likely that the behavior will occur again. There are two categories of consequences within operant conditioning, *reinforcement* and *punishment.* Consequences are reinforcing if they increase the likelihood of a behavior's occurrence in the future; alternatively, consequences are punishing when they reduce the probability of future occurrence.

Social Learning Theory

Behavior modification is also founded upon Albert Bandura's social learning theory. According to social learning theory, an individual's behavior may be affected by observing the behavior of others. Children and adults learn by witnessing the consequences of others' behavior. An underlying principle of social learning theory is modeling, which suggests that people are more likely to engage in behaviors they observe other people perform if those individuals receive desired consequences.

Ecological Systems Theory

An ecological perspective, proposed by Uri Bronfenbrenner, contends that behavior is influenced by conditions existing in the individual's immediate environment, surrounding environments, and experiences occurring in the larger social, economic, and cultural contexts. Within this approach, individual capabilities are assessed in relation to environmental demands. Consistent with this framework, behavior modification strategies also explore how experiences within one's environment affect behavior. Not only are antecedents and consequences viewed within the individual's immediate setting (e.g., classroom), but their effects can be apparent from events that occurred in a previous setting (e.g., home). In particular, *setting events* are experiences in previous settings that set the stage for a particular behavior in a later setting. For example, a child who did not eat breakfast at home may find it harder to stay on-task in class during the school day.

Behavior Modification Techniques

There are two primary ways of altering an existing environment to modify behavior: adding or removing stimuli from the environment. Positive consequences add stimuli to the environment after the behavior has occurred; negative consequences remove stimuli after the behavior has occurred. Along with the positive and negative aspects to consequences, there are two distinct categories of consequences: reinforcement and punishment. Accordingly, there are four types of consequences: (1) positive reinforcement, (2) negative reinforcement, (3) positive punishment, and (4) negative punishment. Each of these consequences can be used to modify behavior. To be most effective, reinforcement and punishment should be implemented *contingent* upon a specific behavior.

Increasing a Desired Behavior

Increasing behavior utilizes reinforcing consequences, or consequences that, when applied, increase the likelihood that the behavior will occur again in the future. By definition, reinforcement always increases behavior. Thus, it is technically incorrect to state that reinforcement does not work; a consequence is not reinforcing if it does not increase the behavior. Furthermore, even though the terms are commonly used interchangeably, the terms *reward* and *reinforcement* are

not synonymous. A reward is given after a behavior occurs; however, unlike reinforcement, it does not necessarily have the effect of increasing the behavior.

Behavior modification uses two types of reinforcement to increase behavior: positive and negative reinforcement. *Positive reinforcement* is a stimulus added to the environment after a behavior occurs that increases the probability the behavior will occur again. Positive reinforcement can include any stimulus, but often takes the form of verbal praise, tangible objects, or social attention. For example, if saying "Good job" to a child increases the number of math problems completed, then the verbal praise positively reinforces the completion of problems. A behavioral principle related to positive reinforcement is the *Premack principle.* Often referred to as "Grandma's rule," the Premack principle states that a low probability behavior is more likely to occur if it is paired with a high probability behavior. This is similar to your grandmother telling you that you can eat your dessert (high probability behavior) after you eat your vegetables (low probability behavior).

Additionally, behaviors can be reinforced by removing stimuli from the environment. *Negative reinforcement*, or escape conditioning, increases a behavior by removing something aversive from the situation. An everyday example occurs when an individual takes an aspirin to alleviate pain from a headache. If the individual continues to take aspirin for future headaches, it is considered negative reinforcement because the behavior of taking aspirin increases as the result of the pain being removed.

Decreasing an Unwanted Behavior

Consequences that reduce the likelihood of a behavior occurring are called *punishers.* In reducing unwanted behaviors, punishers can be added or removed from the environment. To be most effective, punishment should be immediate, continuous, and intense.

Positive punishment occurs when an aversive stimulus that reduces behavior is added to the environment. Spanking a child is an example of positive punishment. The act of spanking is added to the situation and results in a decrease in the child's previous behavior.

In contrast, *negative punishment* reduces behavior by removing a pleasant stimulus after the behavior occurs. A common example of a negative punishment is "time-out." During time-out, a child is removed from a desired setting for a short period of time because of having performed an unwanted behavior.

The removal of the desired stimulus (e.g., parent attention) serves as a punishment because it reduces the child's previous unwanted behavior.

In addition to these forms of punishment, behaviors can be reduced through *differential reinforcement.* Through this technique, an unwanted behavior is ignored, and another behavior that is an alternative to or incompatible with the undesired behavior is reinforced. An example of this procedure is to reduce running in school hallways by reinforcing walking in the hallway. Walking and running are incompatible behaviors: one cannot occur in the presence of the other. Thus, by reinforcing walking, the unwanted behavior of running is reduced.

Reinforcement Versus Punishment

Behavior management programs tend to focus primarily on reinforcement instead of punishment, despite research demonstrating the effectiveness of punishment. The use of punishment is ridden with multiple limitations, including that (a) it does not teach appropriate behaviors, (b) it does not eliminate or counter reinforcement for behaviors, (c) it can become reinforcing to those administering the punishment, (e) it may negatively affect the behavior of other individuals, and (f) some forms of punishment may be considered ethically questionable. A common behavior management technique used in educational settings is positive behavior support, which focuses on developing appropriate behaviors in students through the use of positive reinforcement. Punishment is still used in combination with reinforcement strategies, but it is typically a secondary component to the behavior management program.

Setting Up a Behavior Modification Program

There are five major steps in developing and implementing a behavior modification plan. These steps include developing behavioral definitions, conducting a functional assessment, collecting data, implementing the program with fidelity, and evaluating the effectiveness of the program.

Behavior Definitions

The first, and one of the most important, components of setting up an effective behavioral modification plan is defining the behavior in appropriate

terms. The behavior to be altered should be defined in terms that are specific, observable, and measurable. The definition should be specific so that anyone observing the individual can easily identify the target behavior. Next, the definition must be in terms that are observable to the individual recording the behavior. Finally, the behavior must be defined in a way that can be quantified to evaluate the effectiveness of the program.

Functional Assessment

A major principle within behavior modification is that all behavior is purposeful. Thus, a key component to developing a behavior modification program is to perform a functional assessment of the behavior identified to be altered. A functional assessment gathers information and develops hypotheses for the intended purpose of the behavior. Information gathering includes conducting interviews and performing behavioral observations in naturalistic settings, such as classroom, playground, or home environments. Interviews provide a means of obtaining anecdotal information regarding the strengths and needs of a child and a preliminary assessment of the behavior in different settings. Conducting observations serves as a way to empirically assess the frequency, duration, or intensity of the behavior and to provide an indication of the antecedents and consequences of a particular behavior (e.g., A-B-C assessment). After information from interviews and observations are analyzed, functional hypotheses of the behavior are derived. Through this process a more appropriate alternative, or replacement behavior, can be identified that serves the same function as the behavior to be modified. A term commonly associated with functional assessment is *functional analysis.* Functional analysis is a process that follows the procedures of functional assessment; however, it extends the process by empirically testing the functional hypotheses to scientifically determine the purpose of the behavior.

Data Collection

All procedures within behavior modification programs are founded on data-based decision making. Throughout the process, data are collected through observations and recorded using behavior observation charts. Before an intervention is implemented, data are collected to provide an estimate of the behavior

(e.g., baseline data). Data collection continues through intervention and follow-up phases to determine if the intervention was successful. Effective data collection is dependent on a specific, observable, and measurable definition of the behavior. Consistency is critical in the collection of data throughout a behavior management program. If more than one person is performing observations and collecting data, then procedures to ensure interobserver agreement must be followed. It is important to evaluate whether the individual observers were using the same observation procedures and recording the behavior in the same way.

Treatment Fidelity/Integrity

Treatment integrity refers to the degree to which an intervention was implemented as intended. It is critical that all participants in a behavior management program implement the procedures in a complete and consistent fashion. Many interventions do not produce desired results, solely because of an inability to consistently implement all components of the program. Measures should be taken to effectively evaluate the degree of treatment fidelity that has been implemented.

Evaluation

Finally, behavior management programs should establish procedures to evaluate the effectiveness of the intervention. The process of evaluation should not be considered a one-time event but rather a continuous process throughout the program. In this way, program evaluation provides a means to modify the program based on immediate information. It also allows the steps of the behavioral management program to be cycled through again whenever needed. Evaluation procedures often include graphing the data collected during baseline and treatment phases. The effectiveness of the program is determined based on visual inspection of the graphed data and statistical analysis. Follow-up data should be collected to determine if the effects of the program are maintained over time. Comprehensive evaluations also include an assessment of social validity, or the extent that the program enhanced the child's quality of life.

BELL CURVE

The term *bell curve* has several meanings. One meaning is that of a statistical distribution, termed the *normal distribution*, which was identified by Carl Friedrich Gauss. Its shape is that of a bell. The other meaning comes from a book title.

This latter meaning of the bell curve relates to one of the most stimulating and controversial books published in the past two decades, written by Richard Herrnstein and Charles Murray, and titled *The Bell Curve: Intelligence and Class Structure in American Life.* This volume engendered a national conversation and even widespread debates about controversial issues, such as racial and ethnic group differences in intelligence test scores, the respective roles of nature versus nature in influencing intelligence, and the meaning of intelligence.

The primary thesis of this 845-page tome is that American society is undergoing a process of social stratification that is being determined by IQ. Herrnstein and Murray posited that there is emerging a "cognitive elite," a social group composed of highly intelligent people constituting the highest socioeconomic class, and that less intelligent people are gravitating to the lower socioeconomic classes. According to Herrnstein and Murray, a major problem with such social stratification based on IQ is that there will likely be less upward mobility for many individuals from lower socioeconomic classes, because highly intelligent individuals tend to marry highly intelligent individuals rather than less intelligent individuals.

The Bell Curve thus addressed the relationship of IQ to class structure in American life. It posited that success in life is largely based on inherited differences in cognitive ability among people. It also presented findings and commentary on the relationship between race and intelligence.

Although Herrnstein and Murray reviewed many empirical studies in their book, the most important source of data that they examined and discussed is the National Longitudinal Survey of Youth (NLSY), a longitudinal survey of American youth with a very large sample (originally 12,686 youth, ages 14–22). These youth were graduates of American high schools between 1980 and 1982. Herrnstein and Murray carefully reported on various extensive analyses of this data source in the various chapters of their book, *The Bell Curve.* Throughout the book, they used analyses of the NLSY data source to attack various programs of social assistance; these attacks, in turn, ignited widespread debates.

Herrnstein and Murray grounded their work on a traditional view of intelligence based on certain propositions:

1. There is a general factor of cognitive ability on which individuals differ.

2. IQ tests measure intelligence more accurately than do aptitude and achievement tests.

3. IQ tests measure what most people view to be intelligence.

4. IQ scores are relatively stable over much of human life spans.

5. IQ tests tend not to be biased against economic, ethnic, racial, or social groups.

6. IQ is substantially heritable, with 40% to 80% of the variation in IQ scores being attributable to hereditary factors.

There are numerous conclusions resulting from the extensive analyses in their work. Regarding poverty, Herrnstein and Murray concluded that IQ is a stronger predictor of poverty than is socioeconomic background. Regarding unemployment, they concluded that low IQ is a greater risk factor than either education or socioeconomic background. Regarding children born out of wedlock, they found that low IQ for a woman increases the likelihood that the woman will have an illegitimate child. Regarding welfare dependency, they determined that low IQ is a prominent predictor of the receipt of public welfare funds among women. Regarding parenting, they found that low IQ among White mothers is a strong predictor of low birthweight among children. Regarding crime, they concluded that low IQ is a risk factor for criminality.

Regarding ethnic differences, they concluded that Americans of East Asian background (e.g., Japanese Americans, Chinese Americans) tend to have higher IQ scores than Euro-Americans who, in turn, tend to have higher IQ scores than African Americans and that the gap in IQ scores between Euro-Americans and African Americans has narrowed by about three IQ points. They also determined that the difference in family income between Euro-American families and African American families is markedly reduced when one controls for IQ. Regarding social problems, they determined that individuals with social problems tend to be low IQ individuals. In general, Herrnstein and Murray contended that intelligence affects many social and psychological attributes of individuals with high IQ, having many more salutary effects on high IQ people than on low IQ people.

If higher intelligence is a protective factor against numerous social ills, then what about efforts to raise intelligence? Herrnstein and Murray reviewed research on efforts to improve intelligence and found that initiatives to improve nutrition, formal schooling, and preschool education may have positive effects on intelligence but that the research on such initiatives is thus far inconclusive. However, they strongly support adoption at birth for children from problematic family settings to good family environments as the major way to improve the intelligence of children.

One noteworthy feature of their book is that the vast majority of the data that they analyzed dealt with Euro-American individuals—especially, Euro-American females. As a result, it is improper to view it as a tome primarily concerned with ethnic and racial group differences in IQ. *The Bell Curve* is, however, an exposition of a theory of cognitive stratification of American society.

Herrnstein and Murray predict certain specific trends in American society. First, the cognitive elite will become increasingly isolated. Second, the cognitive elite and the affluent will merge to become the new upper socioeconomic class. Third, the quality of life for the people in the lower half of the IQ distribution will deteriorate.

To address the social problems resulting from the cognitive stratification of society, Herrnstein and Murray contend that certain changes should occur in government. First, the rules that underlie starting and running a business should be simplified, so that more people from all levels of society can make a viable living and find valued places in society. For example,

the enormous federal tax code should be simplified. Second, the criminal justice system should be simplified, clearly indicating the meanings of criminal offenses and their consequences.

The Bell Curve has engendered much subsequent inquiry on intelligence and even strident academic debate.

BILINGUAL EDUCATION

While there are about 200 recognized sovereign nations, there are well over 6,000 languages spoken throughout the world. Because of increased migration, geographical proximity, and/or political conquest and colonization, few countries today can claim monolingualism as the norm. Moreover, globalization has placed English in a unique role in many school systems throughout the world. Bilingual and multilingual education is one form of schooling that has been developed worldwide in response to this linguistic and cultural diversity.

The terms *bilingual students* and *bilingual education* are sometimes confused. Bilingual children know and use two languages to different degrees. Depending on the nature of access to both languages, as well as attitudes toward the languages, bilingual children demonstrate varying proficiency in their two languages; for example, they may speak both languages

but be literate in only one language. Their bilingual skills and the extent they identify culturally with the two languages may develop and vary over time. Bilingual children may or may not attend a bilingual education program.

This entry outlines bilingual and multilingual education for minority (dominated) language and majority (dominant) language speakers, using examples from nations throughout the world. After introducing some basic definitions of key terms, the entry highlights various models that are traditionally distinguished. The third section addresses issues and trends related to the implementation of bilingual education programs.

Definitions

Simply defined, *bilingual education* is instruction that uses two languages as media of instruction. By extension, multilingual education programs aim for proficiency in more than two languages. These programs are implemented in many different forms in countries all over the world and respond to national and local contexts, student needs, and available resources.

In this entry, *native language* will be used to refer to the language in which the child has been raised, although it must be noted that in multilingual environments this can be more than one language and it may not always be the same variety as the (standard) language variety taught in school. The dominant or societal language is the predominant language used for communication in the students' nation (including government, education, media). It generally has a high-status standard variety that is used and taught in schools. A *second language* is a language learned at a later stage than the native language. This often occurs outside the home through school or the media. *Heritage language* is the language used by a particular ethnic group. *Minority* or *dominated languages* are languages used by language groups who are politically and socially placed in a minority situation but may not necessarily be numerically in the minority. In many school districts in the United States, Spanish is a minority language even though Spanish-speaking students may constitute the largest student group. *Majority language* speakers are speakers of the dominant, or societal, language. They are increasingly a numerical minority in urban schools.

The definition of bilingual education as instruction in and through two languages does not consider foreign language classes as a form of bilingual education because, even though some form of bilingual proficiency is reached, the foreign language is only taught as a subject. This entry also excludes out-of-school efforts for native language maintenance through community-based organizations that complement monolingual education in the societal language; although this situation results in de facto bilingual education, both languages are not used within the same instructional approach. Finally, it must be noted that much research has described bilingual education at the elementary grades, though interest in preschool and secondary models is increasing.

Bilingual and Multilingual Models

Many different classifications and descriptions of bilingual and multilingual education programs exist. Three broad criteria distinguish among the most commonly implemented models: *program goals, target population*, and the *distribution of the languages*. In terms of goals, some programs aim for additive bilingualism or multilingualism; that is, the program's goal is to add one or more new languages to the student's native language. In contrast, subtractive models are bilingual approaches where the main goal is to facilitate the learning of the societal language. A second criterion that distinguishes among various models is the student population. Many programs enroll native speakers of the societal language and teach them a second or third language. Other programs exclusively target speakers of dominated languages, including regional and immigrant languages. Few bilingual programs enroll a dual target population of native speakers of the societal and a dominated language. Some bilingual programs purposefully integrate students from different language groups for certain times of the day or week. The third criterion considers the use and distribution of the two or more languages for instructional purposes. The amount of time allocated to teach language and the subjects to be taught in each language is directly related to the goal and target population. The choice of the language(s) of initial literacy instruction is also a key decision in bilingual and multilingual programs.

Table 1 summarizes some of the most common program labels used in the literature. Bilingual and multilingual programs can be programs within schools, or they can be schoolwide. A program label can represent only a general description of a bilingual or multilingual program. The actual implementation of

Table 1   Bilingual and Multilingual Program Models

Program Label	Language Goals	Target Population	Language Use and Distribution
Multilingual education	Multilingualism	Minority, majority	L1, L2, and L3
European schools	Multilingualism	European Union civil servants	L1, L2, and L3 (and optional L4)
Mainstream bilingual education	Bilingualism	Majority, international	L1 and L2
Canadian immersion programs	Bilingualism	Majority	L2 and then L1
Two-way immersion	Bilingualism	Minority, majority	Long-term L1 and L2 use
Maintenance bilingual/ heritage language education	Bilingualism	Minority	L1 and L2
Bilingual education for the deaf	Bilingualism	Minority	L1 and L2
Transitional bilingual education	Proficiency in L2	Minority	L1 for limited amount of time and L2
Integrated transitional bilingual education	Proficiency in L2	Minority	L1 for limited amount of time and L2

Source: Adapted from Brisk, M. E. (2006). *Bilingual education: From compensatory to quality education* (2nd ed.). Mahwah, NJ: Erlbaum; and Baker, C. (2006). *Foundations of bilingual education* (4th ed.). Clevedon, UK: Multilingual Matters.

each model can vary widely depending on the availability of qualified teachers, resources, official policies, and societal and school (district) attitudes.

Bilingualism for Societal Language Speakers

Programs for native speakers of the societal language are typically enrichment programs, that is, optional programs for parents who want their children to develop high levels of bilingual competence. Generally speaking, these programs cater to children from higher socioeconomic backgrounds and are associated with *elite* or *elective bilingualism.* Elite bilingualism is largely uncontroversial and supported as an enrichment possibility for majority language speakers for personal development and access to global economic opportunities. Two bilingual program options that have been developed for societal language speakers are mainstream bilingual education and (Canadian) immersion programs. Multilingual models are found at the school level (the European School model and other schools) as well as the country level.

Mainstream bilingual education often takes place in the students' native language and an international language, such as English. International schools have traditionally served an elite, often mobile population through monolingual instruction. The increased enrollment of non-English-speaking international and local students has led to more bilingual or multilingual schools where English and the societal language are taught. International schools in Brazil use Portuguese Brazilian in the morning and English in the afternoon and often hire teachers from Brazil and North America.

Probably the best-known bilingual enrichment programs for dominant language speakers are *Canadian immersion programs.* (The term *Canadian* is added to distinguish these bilingual programs from English immersion programs for minority students, which aim for second language proficiency rather than bilingualism.) French immersion programs were developed in the late 1960s in response to demands from middle-class, Anglophone parents living in predominantly French-speaking Montreal, Quebec, to provide their children with the opportunity to develop a functional level of bilingualism. Immersion models differ with regard to the introduction of the second language (early versus late immersion) and the amount of time

spent in the second language (full or partial immersion). In early, full immersion programs, the target (second) language, French, is introduced before the student's first language during the first two years of elementary school. By third grade, the student's native language (English) is formally introduced in the curriculum, and both languages are used for equal amounts of time for the rest of the program. In the case of late immersion, the second language is introduced either at the upper elementary (middle immersion) or at the secondary level (late immersion). In Hungary, English is introduced as a medium of instruction at the secondary level, alongside Hungarian. Canadian-style immersion programs can be found as elementary foreign language immersion programs in the United States in Chinese, French, Japanese, or Spanish.

The *European school model* is a multilingual model originally designed for children of parents who worked for the European Coal and Steel Community. There are now 10 European schools in Luxembourg, Belgium, Germany, Italy, the Netherlands, and Great Britain, primarily enrolling the children of civil servants working for the European Union. The schools follow a common model with two main goals: to maintain and develop the students' native language and cultural identity and to promote a European identity. The European school model begins with extensive instruction in the students' native language and a second language initially as a subject area. By second or third grade, the second language use as a medium extends to subjects that are less language-dependent. Academically complex instruction in the second language is gradually increased until by eighth grade, subjects such as science and history are taught in and through the second language. European identity development is supported through common "European hours" during which students from multilingual backgrounds engage in cooperative and hands-on learning of content taught from a European perspective.

In some European countries, multilingual models are implemented wherein a high prestige language is added to a bilingual education program or three languages are used as media of instruction. Catalan immersion programs for native Spanish speakers include Catalan and Spanish, as well as English as a third language. In Switzerland, private schools offer bilingual streams in German and French. English is used to teach subject matter and cultural activities as of seventh grade, and students can add Latin or Italian

in later years. Luxembourg has official trilingual education for all students enrolled in the school system. Mandatory preschool education begins in Luxembourgish, and this language continues as a language of instruction and as a subject throughout elementary school. German is introduced as a subject the first year of primary school and then intensifies as a subject and medium of instruction until sixth grade. Similarly, French is introduced as a subject in second grade and then increases its role in the curriculum to be the exclusive medium of instruction by the age of 15. Foreign language education is introduced at the secondary level as well, including English, Latin, Spanish, Italian, or Greek. A trilingual policy also shapes the education system in India, where students are expected to learn the regional language, Hindi, and English, regardless of their native language.

Bilingualism for Dominated Language Speakers

Dominated or minority language speakers generally do not have a choice in becoming bilingual. For these groups, learning a second language is necessary for survival and access to the society in which they live as a result of forced migration, conquest, or voluntary immigration. This form of bilingualism is often referred to as *folk* or *circumstantial bilingualism* and, unlike elite bilingualism, it is often controversial in educational policy. In recent years, speakers of regional and indigenous languages have received more legal protection through national and international law. Similar linguistic rights do not yet exist for immigrant or ethnic languages. As a result, the position of indigenous and regional minority languages and ethnic or immigrant languages in school varies.

The consistent repression and rejection of the use of indigenous languages in schools as part of the nation-building process has been documented throughout the world. In the United States, the 300 Native American languages that existed upon European contact have been reduced to only a small number of languages still widely spoken by children today. Until recently, European national governments have largely ignored regional language groups with long-standing historical and cultural roots in the area (such as Catalan in Spain, Frisian in the Netherlands, Welsh in Wales) or even actively prohibited the use of these languages in school, as was the case for Basque under General Franco's regime in Spain. As

a result, fluent speakers of these indigenous languages and regional minority languages have been disappearing rapidly. *Heritage* or *bilingual maintenance* programs have been established to revitalize these indigenous and minority languages to increase the number of speakers, expand the domains where the language is used, or both.

The Māori in New Zealand provide full immersion in the minority language in preschool (through Te Kōhanga Reo programs or "language nests") and elementary school (Kura Kaupapa Māori) before introducing English as a medium of instruction. A similar approach was chosen to revitalize the Hawaiian language. In Bolivia, after many years of repression, Quechua and Guaraní are now used as media of instruction. With an emphasis on community involvement, indigenous languages and cultural practices are included in the curriculum in several South American countries, in addition to the official language, Spanish. In the United States, language revitalization efforts are particularly strong for Native American languages. Teresa McCarthy describes the history of Rough Point, Arizona, a Navajo–English bilingual program. Subjects are taught in both English and Navajo through second grade. As of third grade, English becomes a medium of instruction, and Navajo continues to be used as a vehicle for studying Navajo culture and citizenship.

Language maintenance and revitalization efforts in non-English-speaking countries increasingly include a multilingual component through the addition of a third, high-prestige language such as English, to the regional minority language and the societal language. In the Basque region (Spain), the Basque language is used as a medium of instruction from kindergarten through secondary school. Spanish and English are initially included as a subject at the elementary level; English is then also used as a medium of instruction at the secondary level. German or French are offered as optional foreign languages. In the Netherlands, schools are experimenting with the equal distribution of Frisian and Dutch and the introduction of English as a medium of instruction in fifth and sixth grades.

Bilingual programs for the deaf teach content through sign language and the written form of the societal language. Approaches to language (the use of different sign systems) and the curriculum vary greatly from program to program and is often constrained by teachers' lack of proficiency in sign language. Deaf culture and identity are important components of the bilingual program to counter deficit views of individuals who are deaf or hard-of-hearing.

In most nations, *transitional bilingual education* (TBE) is the model most commonly chosen for ethnic and immigrant languages. In a TBE program, the student's native language is used for an initial period of literacy development and content learning to assist the students' transition to literacy and content learning in the societal language. The goal is not to maintain or develop the students' native language but to provide access to the language of school. Students are typically expected to enroll in the program for 2 or 3 years and then exit the program into a standard classroom or instruction in the societal language only (early-exit TBE). In most African postcolonial nations, bilingual education that includes the student's native language is transitional and often experimental in nature. Other TBE programs attempt to provide a more gradual transition (late-exit TBE). Students begin literacy and content instruction in their native language, with English as a second language instruction. In second grade, formal literacy instruction in the second language is started. In third grade, instruction is increasingly balanced between the two languages across subjects; often the native language is used to preview major concepts and activities which are later taught to students in English. Academic English instruction continues to increase by the second half of third grade and students are expected to exit the program at the end of fourth or fifth grade.

Integrated Bilingual Education Models

Few bilingual models address the need for bilingualism or multilingualism for an integrated minority–majority student population. In most cases, the focus is on avoiding the segregation of minority language students while they are becoming familiar with the new language and culture (integrated TBE). The Foyer model in Belgium provides half of the instruction for Turkish-speaking students in preschool and kindergarten separately and half of their instruction integrated with majority language speakers. By third grade, 90% of the instruction is integrated with majority language speakers, and 10% of the instruction is on native language and culture. Integrated TBE models exist in Scandinavia and the United States, where minority language students are separated for specialized instruction in their native language and

integrated with native English speakers for specific subject areas for varying amounts of time.

The most developed integrated bilingual education model is *two-way immersion* (TWI) education. In the United States, TWI is an integrated model of bilingual education according to which native English speakers and native speakers of a minority language are educated together for most or all of the day and receive content and literacy instruction through both English and the minority language. Its goals include academic achievement, bilingualism and biliteracy development, and cross-cultural competence for all students. TWI programs vary by the distribution of the heritage and the societal language. Some programs start with literacy and content instruction in the minority language for 90% or 80% of the time; others distribute the two languages more evenly.

Issues and Trends in Multilingual Education

The existence of various bilingual education models reflects the basic principle that quality education through multilingual approaches can and needs to occur in different ways to respond to international, national, and local goals and needs. Despite these multiple realities, the term *bilingual education* is often used to serve particular political and ideological ends. Supporters of English-only policies, for example, limit the term to instruction exclusively in the native language. Bilingual education advocates sometimes argue that the term should be applied only to programs in which the two languages have equal status and are used equally for teaching. Both definitions are narrow in scope and exclude the realities and multiple approaches to multilingual development that exist.

The two definitions also reflect a dichotomy that has often hindered systematic research that can inform effective program implementation. Much research on bilingual education has attempted to justify either the use of the native language (in addition to the societal language) or solely the societal language. Whereas this debate has resulted in many, highly contested program evaluation studies, it has contributed little to the understanding of the factors that contribute to positive linguistic, sociocultural, and academic outcomes in schools. To guide program implementation, it is necessary to consider the interaction between theoretical principles and the dynamics of language and cultural practices in real schools and classrooms. Studies have found that effective schooling for language minority students comes from additive bilingual programs that are fully integrated in the school, taught by quality teachers, and guided by knowledgeable leadership. These programs have bilingual curricula that reflect high expectations of students, use bilingual teaching methodology and assessment practices, and have strong parent and community involvement.

The perceived problematic nature of bilingual programs for minority language speakers contrasts sharply with the desirability and value of multilingual proficiency for speakers of the societal language. These conflicting positions exist within diverse nations and point to a double standard in educational language planning. Whereas language majority speakers are encouraged to expand their linguistic repertoire beyond their native language, speakers of minority languages have to struggle to maintain their native languages and prevent them from dying out. The double standard results in a dual education system: one that values and actively promotes bilingualism (for the elite) and one that rationalizes the importance of (monolingualism in) the societal language (for language minority students). France promotes foreign (i.e., official European Union) languages for its native French-speaking population but fails to provide bilingual education options that use immigrant languages such as Turkish.

Bilingual and multicultural education is increasingly shaped by globalization and the role of international languages in education, in particular English but also Chinese, Arabic, and Spanish. In Canada, high school students in Ontario view French as a commodity that can provide access to economic opportunities beyond the local community into the international marketplace. The positioning of English and other international languages within and across nations plays an important role in multilingual education. Competition with English or other international languages can undermine the availability of quality instruction in and through indigenous or ethnic languages in non-English-speaking countries. In Taiwan, the government established policies to promote Taiwanese and English, but an analysis of the actual implementation of the policies showed that teacher training and curriculum and resource development occurred for the English language but not for Taiwanese (or other minority languages). English is also taking over functions and domains traditionally reserved for the societal language, particularly in business and scientific discourse, which may cause

language shift or loss over time. Unequal access to multilingual instruction that supports native language instruction and adds not only the societal language but also English may constrain educational opportunity and social mobility.

Bilingual and multilingual education models challenge monolingual norms and practices that are prevalent today. In the United States, the federal No Child Left Behind Act and recently passed English-only laws in California, Arizona, and Massachusetts rejected the value of multilingualism for its language minority population by insisting on English-only instruction and the assessment of achievement through English. The monolingual bias reflected in these laws views multilingualism as an abnormality rather than a global reality and treats multilingual resources as a deficit rather than a resource. By bridging the divide between elite and minority bilingual education practices, schools can build on and extend existing linguistic and cultural resources to meet current and future language, cultural, political, social, and economic demands and develop multilingual competence for all students.

BILINGUALISM

Bilingualism is a major fact of life in the world today. One in three of the world's population routinely uses two or more languages for work, family life, and leisure. Many more make irregular use of languages other than their native one(s), including those who have learned an additional language at school and use it occasionally for specific purposes (e.g., travel). It seems likely that this trend will continue given the current processes of globalization and the growing need to communicate across political and linguistic borders.

The term *bilingualism* can be used to describe an individual phenomenon, as in a person's ability to speak two or more languages. It is also possible to talk about bilingualism as a characteristic of a group or community of people, as bilinguals and multilinguals are usually found in groups, communities, or particular regions. In this entry, the discussion of bilingualism focuses on the individual level. The entry commences with a definition of individual bilingualism, followed by a discussion of related dimensions and characteristics. It then provides an overview of the reported advantages of bilingualism and concludes

with a description of the factors associated with the development of bilingualism in infancy and beyond.

Defining Bilingualism

The concept of bilingualism has broadened since the beginning of the 20th century. Although earlier definitions tended to restrict bilingualism to equal mastery of two languages, it is now recognized that a bilingual or multilingual speaker uses different languages for different purposes, in different contexts, and in communicating with different partners and does not necessarily possess the same level or type of proficiency in each language. The broadening of the concept of bilingualism is largely due to the realization that the point at which a speaker/user of two languages becomes bilingual is either arbitrary or impossible to determine.

Despite its omnipresence, defining bilingualism, or a bilingual individual, proves to be more difficult than it appears. The term *bilingual* describes primarily someone who can function in two languages in conversational interaction. It can also include the many people in the world who use, and have varying degrees of proficiency in, three, four, or more languages. In his definition of *bilingualism*, François Grosjean focuses on the daily use of two or more languages and distinguishes bilinguals, who use two or more languages in daily life, from "dormant bilinguals," who retain knowledge of different languages but no longer use them in daily life.

Describing Individual Bilingualism

According to linguist William Mackey, bilingualism is a behavioral pattern of mutually changing linguistic practices that vary in degree, function, alternation, and interference, or cross-linguistic influence. It is through these four related characteristics that individual bilingualism may be best described.

Degree. Because bilingualism is a relative concept, it involves the question of degree. In describing a person's bilingualism, the most obvious thing to determine is how well an individual knows the languages he or she uses. Because bilinguals are rarely equally fluent in all language skills in all of their languages, this would involve separate assessments of comprehension and expression in both the oral and written forms of each language. In this way, ability in two or more languages is best understood on a dimension or continuum, with dominance and development varying across people. For example, some bilinguals actively speak and write in both languages. This is referred to as productive competence. Others have more passive, or receptive, ability in a language, such that they may understand or read it but may not be able to speak or write it very well. Ability in each domain may be relatively advanced in both languages or may just be developing in a second or third language.

Furthermore, it is necessary to determine a bilingual's mastery of speech sounds or graphics, grammar, vocabulary, meanings, and discourse in each skill for each language, as a bilingual's mastery of a skill (i.e., listening, speaking, reading, and writing) may not be the same at all linguistic levels. For example, a bilingual may have an extensive vocabulary but a poor pronunciation, or a native-like pronunciation but underdeveloped grammar. In effect, proficiency in two sets of related variables, skills, and levels needs to be determined. This framework highlights the complexities involved in defining and understanding individual bilingualism, while at the same time it belies the existence of great within-group diversity.

Bilinguals are sometimes expected to be two monolinguals in one person. Grosjean referred to this as the monolingual, or fractional, view of bilinguals. He argued that the bilingual is not the sum of two monolinguals but has a unique linguistic profile that is a complete linguistic entity, an integrated whole. This is because bilinguals do not usually possess the same competence as monolingual speakers in both of their languages because bilinguals use their languages with different people, in different contexts, and for different purposes; furthermore, levels of proficiency in a language may change over time according to changing circumstances and linguistic contexts. Communicative competence in one of a bilingual's two languages may be stronger in some domains than in others. As Grosjean noted, this is natural and to be expected.

Function. Mackey argued that bilingualism is not a phenomenon of language but a characteristic of its use. Use is an important factor in the development and maintenance of bilingualism, as individuals often use their languages for different functions and purposes; these functions, in turn, affect their degree of proficiency in each language. The domains where each language is acquired and used also vary. Functions of bilingualism may be external or internal.

External functions of bilingualism are areas of language contact that vary by duration, frequency, and pressure. Areas of contact include all media through which languages are acquired and used (e.g., in the home, community, school, radio, television, print materials, and other uses of the printed word).

Home language(s) may reflect or differ from those of the community and other language contacts. Bilingual parents may decide to each use a different language with their children, so that one parent uses language A while the other parent uses language B. This practice is often referred to as Grammont's principle, or "one person, one language," and the effects have been studied to test the theory that two languages can be acquired from birth for the same effort as acquiring one. Community languages include those languages spoken in the bilingual's neighborhood, ethnic group, church group, workplace, and social group. The more prevalent language of the greater community often takes the place of the home language as the most important influence on a bilingual child's speech. This presents many challenges for families trying to raise children bilingually in the majority language and a less prevalent one. A person's language contact in school may be with a language taught as a subject (e.g., foreign language class) or with a language used as a medium of instruction (e.g., two-way immersion or dual-language program). The community's support for, and the prevalence of, both languages are important factors in the development and long-term maintenance of each language. Radio, television, movies, music, newspapers, magazines, and the Internet are powerful media in the maintenance of bilingualism. Access to these media may be the key factor in maintaining one of a bilingual's languages, especially if the other language is the only one spoken in the area.

Duration, frequency, and pressure are important variables in the development and maintenance of a language. The amount of time a person has lived in a community that uses, supports, and promotes a language (or languages) will affect that individual's command of the language(s). Languages that are used as mediums of instruction will provide more contact hours than those that are taught as individual subjects. How often a person uses each language is as important as how long he or she has been exposed to and has been using those languages. Finally, language use is affected by the types of pressures associated with it, including economic, occupational, cultural, political, military, historical, religious, and demographic.

Bilingualism is also influenced by a number of internal functions. These include noncommunicative uses, such as counting, dreaming, and note-taking. Some bilinguals may use one of their languages for most or all of their inner expression, whereas others may use different languages for different types of internal expression. Internal functions also include factors that are likely to influence a bilingual's aptitude for using each language. Sex, age, intelligence, memory, language attitude, and motivation are regarded as important factors in the development and description of individual bilingualism.

Alternation. The alternate use of two languages, or codeswitching, within a conversation is a natural phenomenon of bilingualism. Studies in the past 20 years have shown that codeswitching is a highly complex and sophisticated process governed by certain rules and constraints that do not violate the syntax of either language. Codeswitching involves the skilled manipulation of overlapping sections of two (or more) grammars; there is virtually no instance of ungrammatical combination of two languages in codeswitching, regardless of the bilingual ability of the speaker. For example, bilinguals may codeswitch because they are momentarily lost for words in one of their languages, or do not know a word or phrase in one language, or can express an idea more effectively in the other language. Rather than demonstrating confusion or a deficit in their languages, bilinguals codeswitch in practical and purposeful ways, usually when in the company of other bilinguals, in an attempt to express themselves with the vocabulary and grammar available to them and/or with more accurate language. Codeswitching is also a learned behavior, as there appears to be a difference in alternation between bilinguals brought up in "one person/one language" homes and those who have grown up in homes and/or communities where members switch freely between two languages. In many bilingual situations throughout the world, codeswitching has become the norm. In those cases, codeswitching is a general marker of belonging to a mixed group with a multiple identity.

Cross-linguistic influence. Another phenomenon of bilingualism is cross-linguistic influence, or the influence of one language on the other such that features of language A are used while speaking or writing language B. Because not all linguistic features work across languages (i.e., cross-linguistically), this type of influence may result in inaccurate or nonstandard

language. Such influence is also called transfer or interference, although the latter term is considered to be negative and pejorative and reflective of a monolingual perspective of bilingualism. Cross-linguistic application does not indicate confusion on the part of the learner. Rather, it represents worthwhile attempts at communicating and linguistic creativity in the journey of bilingual/second language acquisition and development.

The Advantages of Bilingualism

Current research suggests that there are several overlapping and interacting benefits associated with bilingualism. These benefits encompass communicative, cultural, and cognitive advantages. Sometimes, some social and individual problems are falsely attributed to bilingualism.

Communicative Advantages

Parental Relationships. Bilingual children of multilingual homes are able to communicate in each parent's preferred or dominant language. This may facilitate an optimally close relationship with each parent. In other cases, bilingual children may communicate with their parents in one language and with members of their community or circle of friends in another language. For these families, the native language provides a natural and expressive way to communicate with full intimacy while at the same time providing a link to their past and heritage.

Extended Family Relationships. Bilingualism serves as an intergenerational bridge. Bilingual children who have immigrated to a new country have the advantage of carrying forward the family's heritage language. The monolingual without the heritage family language may feel a sense of alienation from relatives and from the past. When extended family members in another country or region speak only the family's heritage language, bilingualism bridges the generation gap and allows closer relationships, a sense of belonging, and rootedness to develop within the extended family. In this sense, bilingualism contributes to the feeling of family continuity across generations.

Community Relationships. Bilingualism allows for a wider range of communication across people, communities, and beyond. Bilingual children in linguistically diverse communities who study in two-way immersion, or dual-language, programs are able to communicate in the wider community, with school and neighborhood friends, and across continents through Internet communication with pen pals in other regions who speak the target language.

Transnational Communication. Language is one barrier between nations and ethnic groups that sometimes hinders communication and the development of friendly relationships. Bilinguals can act as links, not only within the nuclear and extended family and the community but also across societies. When bilingual people travel within multilingual countries or across borders, their bilingualism allows them to forge relationships with people of different nationalities and ethnic groups that might otherwise have been difficult to establish.

Language Sensitivity. Bilinguals may be more attuned to the communicative needs of their interlocutors, because they must constantly monitor which language to use in different bilingual and monolingual situations. Research suggests that bilinguals may be more empathetic and patient as listeners than are their monolingual counterparts when communicating with others who may not be very proficient in a language.

Cultural Advantages

Bicultural Experience. Because language and culture are inextricably linked, bilingualism provides the opportunity to experience two or more cultures in very authentic ways. The monolingual also can experience multiple cultures, through travel or neighbors or ethnically and linguistically diverse communities, but only as a passive onlooker. To penetrate different cultures and to participate and become involved in the core of a culture require knowledge of the language of that culture. Furthermore, because two languages provide access to a wider cultural experience, there is often a greater tolerance of cultural diversity.

Languages provide unique systems of behavior; folk sayings, stories, histories, and traditions; ways of meeting and greeting; rituals of birth, marriage, and death; ways of interpreting the world; ideas and beliefs; and ways of thinking. Bilingualism provides the potential to actively penetrate the cultures expressed in both languages.

Economic/Employment Opportunities. Bilingualism further provides potential economic advantages. As the global village rises and international trade increases,

bilinguals and multilinguals may be in a relatively strong position in the race for employment.

Cognitive Advantages

Research suggests that bilinguals may have some cognitive advantages, ranging from creative thinking to faster progress in early cognitive development and greater sensitivity in communication. For example, bilinguals may exhibit greater cognitive flexibility in understanding the relationship between objects and their labels. Because bilinguals have two or more words for many objects and ideas, the link between a word and its concept is usually looser for bilinguals than monolinguals. For bilinguals, having two or more words for particular concepts extends the range of meanings, associations, and images. Thus, bilinguals have the possibility of developing more advanced language awareness and more fluency, flexibility, and elaboration in thinking than monolinguals.

"Problems" of Bilingualism

It should also be noted that bilingualism does not come without its share of controversy. Some social and individual problems continue to be falsely attributed to bilingualism. For example, bilingualism is sometimes blamed when young bilinguals exhibit language or personality problems. However, these "problems" tend to be temporary and/or related to broader issues of language attitudes and monolingual perspectives to language development. Another, equally complex issue is the question of identity. Identity is not a problem for many bilingual individuals, who either navigate both languages and cultures effectively or who identify more closely with one language and culture while still valuing and using the other. But some bilinguals (e.g., immigrants) feel the pressure to assimilate and identify with the new country exclusively. This may mean losing the identity of their native country and, possibly, the native language. Again, this "problem" is associated more with monolingual perspectives of bilingualism (where monolingualism represents the natural or normal case of language development, and only one language and culture, usually the majority or mainstream one, must take precedence) than with bilingualism itself. Like bilingualism, identities change and evolve over time, with varying experiences, interactions, and collaborations within and outside a language and cultural group.

The Development of Bilingualism

Given sufficient motivation and opportunity, all normally developing individuals can learn more than one language. The development of bilingualism in children can occur in various ways. Simultaneous or infant bilingualism refers to a child acquiring two languages at the same time from birth, or at least from a very young age. Simultaneous acquisition is often associated with the "one person, one language" principle. Other children hear one language in the home from birth and come into contact with another language later, in the neighborhood, wider community, or school, or as a result of immigration to a new country. This is termed *consecutive* or *sequential bilingualism*. Age 3 is generally regarded as an approximate borderline between simultaneous and sequential bilingualism. There is a large literature on the specifics of childhood bilingual and second-language acquisition, including both natural acquisition conditions and those that occur formally at school. The following section provides an overview of the developmental issues surrounding simultaneous and sequential bilingualism in children.

Simultaneous Bilingualism

Bilingual acquisition is a common and normal childhood experience. It is estimated that two thirds of the world's children grow up in a bilingual environment. Perhaps the most important insight gained from studies on child bilingualism over the past 25 years is that simultaneous acquisition of two or more languages can be characterized as an instance of multiple first-language acquisition. That is, the development of each of the bilingual's languages proceeds in the same way and leads to the same kind of grammatical competence as in monolingual children. Until recently, it was thought that early bilingual development occurred in three stages, moving from mixing the two languages to partial and eventually full language separation. But this framework turned out not to capture the typical developmental pattern of infant bilingualism. Recent research has demonstrated that children as young as 2 separate rather than mix their languages and acquire multiple grammars separately and autonomously.

Children who are learning two or more languages from birth follow the same general pattern as children who are learning one. For bilinguals and monolinguals alike, language acquisition begins at birth or

perhaps even before. During the first year, children pass through several important stages in their language development. Like their monolingual counterparts, bilingually developing babies engage in different types of vocal play, like cooing and babbling, within this first year through which they learn to coordinate their muscles and try out different sounds. At about 1 year, bilingually developing children assemble a vocabulary comprising elements from both languages. Type, quality, and amount of exposure to each language influence which words and concepts are learned in which language(s), as well as the developing grammar of each language. By about 18 months, many children begin to string two words together to make phrases. From then on, their utterances develop and progressively become more complex. As children learn about the boundaries of words and express themselves with the vocabulary available to them during this stage, they might overextend or underextend the meaning of words, as well as use elements from both languages. This elementary form of codeswitching represents children's practical and purposeful attempts to express themselves and is not an indication of language confusion. Codeswitching at this stage may also occur when a phrase or word is simpler or is easier to pronounce in the other language. Another phenomenon of early bilingual development is the creation of language boundaries. The bilingual child learns to associate each of his languages with certain individuals, contexts, and/or situations. In these early years, bilingual children, like their monolingual counterparts, are learning at a tremendous rate, experimenting with language and defining and refining usage. Amazingly, within the same time frame as it takes monolingual children to learn one language, bilingual children learn two languages and become adept at using them in socially diverse and appropriate ways.

Sequential Bilingualism

Childhood Sequential Bilingualism. As with simultaneous bilingualism, there are a variety of routes to childhood consecutive or sequential bilingualism. Some children learn the language of the home first and then become exposed to a second language in the community or when they enter school. Other children learn a second language as a result of immigration. Sequential bilingual development in children is very similar to simultaneous acquisition of two languages

if learning takes place in a natural environment (as opposed to formal or classroom language learning). Single phrases and set phrases are developed initially; children concentrate on simple grammatical constructions, over- and underextend vocabulary and grammar, and mix structures from their two languages as they attempt to make sense of, apply, and navigate their developing bilingual repertoire.

A child's second-language development depends on many factors, including the amount and quality of exposure to each of his or her languages at home, in school, in the community, and so forth. If the child's contact with one of the languages is minimal, it will affect that child's opportunities to use the language, which in turn influences eventual attainment of, and proficiency in, that language. Although a child can learn a second language at any age, it is important that the introduction of a second language not come at the expense of the native language. For example, an immigrant child to the United States who enrolls in an English-only educational program upon arrival will, in effect, be taught in an unintelligible language. In such subtractive situations, the child's native language skills may not continue to develop properly, and the child may struggle to attain the necessary second-language skills to cope in the classroom and compete with native language speakers. Thus, the development of both languages is affected.

Current research suggests that children from minority language backgrounds succeed better when they are taught through their native language while gradually acquiring the majority language. In this way, the native language is built upon and serves as the foundation for future learning. The process of language acquisition is a long and complex one; children who are acquiring a new language while also learning grade-level academic concepts and skills benefit from developmentally, culturally, and linguistically appropriate and supportive instruction, including the continued development of their native language.

Adult Second-Language Acquisition. Adults, like children, develop bilingualism in different ways, contexts, and under different circumstances. In summarizing a framework of second-language acquisition, Rod Ellis suggests that there are five interrelated factors affecting the acquisition of a second language: situational factors, input, learner differences, learner processes, and linguistic output. Situational factors refer to the environment of linguistic interactions (e.g.,

classroom context, formal situation, naturalistic setting), the relationship of the interlocutors, and the topic of the conversation. Factors related to linguistic input concern the type of second-language input received (and its comprehensibility) when listening or reading in a second language. Individual learner differences include aptitude, cognitive style, learning strategies, personality variables, and age. Learner processes refer to those learning strategies through which learners consciously and subconsciously process second-language input, as well as production and communication strategies. Finally, second-language output relates to opportunities to engage in meaningful oral and written exchanges with other language users.

Age is a much debated theme in second-language acquisition and development and thus deserves special attention here. Although important questions still remain unanswered, the evidence gathered so far suggests that the human language capacity is subject to maturational changes. Traditionally, the period between 2 years of age and puberty was regarded as the critical period for the development of first and additional languages, although more recent reviews of the research have largely discredited this notion. The concept of a critical period of language development does not mean that language acquisition is not possible beyond the critical period; rather, it suggests that older language learners resort to other cognitive capacities to develop a knowledge system about a new language. In fact, studies have shown that older children and adults can learn a language more quickly and efficiently than younger children can, because their cognitive skills are more developed and they have a more mature linguistic system to build on. However, it does appear that there are advantageous periods for second-language acquisition. One area that may be affected by age is pronunciation. Some studies have demonstrated that native-like pronunciation might be more difficult to attain for languages acquired after puberty, whereas others suggest that the ability to pronounce a second language in a native-like way is not necessarily lost in adulthood. It may be that pronunciation problems of older second-language learners are attributable to difficulty of access to the target language rather than to an outright loss of the relevant underlying capacity to learn additional languages. Although it continues to be a constant source of controversy, the critical period concept has been a valuable construct in the investigation of second-language acquisition across different age groups.

Conclusion

Bilingualism continues to thrive in a world economy with increased ease of international communications. Although an exact definition of who is or is not bilingual remains elusive and ultimately impossible, the concept of bilingualism has broadened thanks to the growing research base on the topic. Much has been learned about the complex social, psychological, cultural, and linguistic factors and processes associated with becoming and being bilingual. Perhaps most importantly, it has been learned that bilingualism is a common, natural, and dynamic phenomenon that will continue to intrigue researchers and the general public alike for years to come.

Bloom's Taxonomy of Educational Objectives

Bloom's Taxonomy is an educational classic. Its formal title is *Taxonomy of Educational Objectives. The Classification of Educational Goals. Handbook I: Cognitive Domain.* A committee of college and university examiners wrote the book, which was edited by Benjamin S. Bloom and published in 1956. Bloom's Taxonomy offered a classification system for educational goals that could be used in the construction of test items and in the formulation of instructional objectives.

The volume presents six categories of educational objectives:

1. Knowledge

2. Comprehension

3. Application

4. Analysis

5. Synthesis

6. Evaluation

Bloom presents sample test items that assess instructional objectives associated with each category of educational objectives along with specific examples of instructional objectives associated with each of the six categories of cognitive objectives.

To Bloom, *knowledge* is defined as "those behaviors and test situations, which emphasize the remembering, either by recognition or recall, of ideas, material, or phenomena" (Bloom, 1956, p. 62). Recognition test items tend to be easier than comparable recall test items, because recognition test items tend to provide incorrect answers along with correct answers (e.g., as with multiple-choice test items). Recall items tend not to provide any answers at all, as the test-taker provides the correct answers to the items.

Bloom clearly acknowledged various forms of knowledge that varied in level of abstractness, from concrete facts to theories and abstract structures. First, there is knowledge of specifics, including terminology and specific facts. Second, there is knowledge of ways and means of dealing with specifics, including conventions, trends and sequences, classifications and categories, criteria, and methodology, Third, there is knowledge of the universals and abstractions in a field, including (a) principles and generalizations and (b) theories and structures. An example of a knowledge objective is "to know the state where New York City is located."

The second category of educational objectives is *comprehension*, which comprises three types of behavior. The first type is translation, which means to transform a communication that is in one form (e.g., a statement in a language, such as English) into a comparable communication that is in another form (e.g., an equivalent statement in a language, such as Spanish). An example of a translation objective is "to graph on graph paper the equation $x^2 + y^2 = 9$." The second type of comprehension behavior is interpretation, which means to formulate a restatement of a communication into another communication. An example of an interpretation objective is "to summarize a short story." The third type of comprehension behavior is extrapolation, which means to make a prediction or to infer an implication or a consequence from a consideration of some statement or communication. An example of an extrapolation objective is "to predict the consequences of implementing a policy of free college tuition for all legal residents."

The third category of educational objectives is application. *Application* refers to using a rule, a principle, or a concept to solve a problem. An example of an application objective is "to solve a distance problem with the use of the Pythagorean theorem."

The fourth category of educational objectives is analysis. To Bloom, *analysis* is "the breakdown of the material into its constituent parts and detection of the relationships of the parts and of the way they are organized" (Bloom, 1956, p. 144). There are three types of analysis behaviors. The first type is the analysis of elements, which refers to breaking down a communication into its constituent parts and identifying the elements of the communication. The second type is the analysis of relationships, which refers to determining the relationships among the elements in a communication. The third type is the analysis of organizational elements, which refers to inferring the organizational principles underlying a communication (e.g., the author's purpose, point of view, or attitude).

An example of an analysis objective is "to infer the view of technology of Mary Shelley in her classic novel *Frankenstein.*"

The fifth category of educational objectives is synthesis. To Bloom, *synthesis* is "putting together of elements and parts so as to form a whole" (Bloom, 1956, p. 162). Synthesis may be viewed as the complement to, and opposite of, analysis.

The products of synthesis behavior fall into three classes: (1) a unique communication, such as a poem or a short story; (2) a plan or proposed set of operations, such as a recipe for how to make use of green pepper slices and pomegranate berries in the same dish; and (3) a set of abstract relations, such as a set of principles for living that interrelate health, a high quality of life, and a limited budget. An example of a synthesis behavior is "to prove the Pythagorean theorem."

The sixth and final category of educational objectives is evaluation. To Bloom, *evaluation* is "defined as the making of judgments about the value, for some purpose, of ideas, works, solutions, methods, material, etc. It involves the use of criteria as well as standards for appraising the extent to which particulars are accurate, effective, economical, or satisfying" (Bloom, 1956, p. 185). The judgments involved in evaluation are based on internal evidence or external criteria. The evaluation of material based on internal evidence addresses features such as "logical accuracy, consistency, and other internal criteria" (Bloom, 1956, p. 188). The evaluation of material based on external criteria makes use of criteria formulated by experts in disciplines or models of excellence in disciplines. An example of an evaluation instructional objective is "to evaluate critically the view of immigration policy suggested in a newspaper editorial."

Knowledge and comprehension are lower-level cognitive objectives, and application, analysis, synthesis, and evaluation are higher-level cognitive objectives. These cognitive objectives form a hierarchy, with knowledge being the objective prerequisite to all other cognitive objectives and evaluation being the objective to which all other cognitive objectives are prerequisite.

Bloom's Taxonomy has informed the writing of achievement test items and the design of instructional programs for decades. It has also inspired subsequent commentaries such as volumes by Lorin W. Anderson and Lauren A. Sosniak, Anderson and David Krathwohl, and Robert Marzano and Thomas Guskey. Bloom's Taxonomy will likely continue to inform educational practice and research in educational psychology.

BRAIN-RELEVANT EDUCATION

Brain-relevant education refers to a relatively new perspective on learning influenced by an abundance of new data emerging from the study of the brain. The term itself—*brain-relevant education*, sometimes referred to as *brain-based learning*—garners criticism by some, who contend that all education relates to, or is based in, the brain. From this perspective, the term may seem pretentious or irrelevant. To others, however, and perhaps the majority, *brain-relevant education* connotes a biological approach to learning. This contrasts with a more traditional position favoring psychological or behavioral emphases.

Other synonymous terms include *education-related brain science*, *educational brain science*, and *educational neuroscience*. Each draws attention to how the brain learns but with particular focus on the biology of learning. This entry uses these terms interchangeably.

Still other similar terms—*neuropsychology* and *biological psychology*—relate neuroscience with psychology more specifically. These subsets of psychology also deal with behavioral oddities and complications resulting from abnormalities in brain structure and function as well as conditioned responses.

The following sections provide a metaview on evolving interest in brain study, relevance of brain science to education, historical background, pertinent philosophical context, themes emerging from brain-relevant education, and pedagogical implications issuing from studies of the brain.

Focus on the Brain

Proclaimed as the decade of the brain by the U.S. government, the 1990s played a significant role in drawing attention to the *science* of cognition. New technology allowed study of the brain in ways not available or practical previously. This technology now makes it possible to see the brain as it functions—an advantage not available in earlier years when study of the human brain was limited to cadaver dissection, on the one hand, and speculation based on interpretation of behavior, on the other.

Methods now commonly used to study live brain anatomy and function include the following techniques and technologies as described by James Kalat.

Imaging of Brain Structure

Computerized Axial Tomography (CT or CAT scan)

In this technique dye injected into the bloodstream creates viewable contrast as x-rays pass through the brain during the scanning process. Resulting photographs can depict structural abnormalities. As this technique utilizes dye injection for contrast, it is classified as invasive.

Magnetic Resonance Imaging (MRI)

This technique applies a strong magnetic field—25,000 times stronger than Earth's magnetic field—in short, repetitive, staccato-like spurts as the subject being imaged passes through a circular tube. Atoms respond to the on–off spurts of magnetism in ways that allow the technology to create images of structures in the brain.

Imaging of Brain Structure and Activity

Electroencephalography (EEG)

By placing electrodes at various locations on the scalp, this technology records electrical activity within the brain. Physicians often provide a sensory stimulus—termed *evoked potentials* or *evoked responses*—to record differences in brain function as a result of the stimulation. This imaging provides approximate location of activity—within about a centimeter of space.

Magnetoencephalography (MEG)

Though similar to EEG, this technique differs in that it measures magnetic fields produced faintly in brain function. This process allows the advantage of observing a given effect in the brain as it travels—somewhat as a wave does on water.

Positron-Emission Tomography (PET)

This technique offers the advantage of high-definition imaging with the added feature of showing hotspots of activity in a live brain. This technique is more invasive that some other brain imaging technologies because it involves injecting chemicals containing radioactive atoms. This fact imposes limitations on the frequency of using this procedure.

Functional Magnetic Resonance Imaging (fMRI)

Similar to MRI, this technique differs in that it detects brain activity based on the presence of oxygen carried by hemoglobin. Both structural and functional imaging result from this procedure.

Fascination with the brain continues well beyond the initial interest stimulated by data revealed with these revolutionary imaging techniques. This is evidenced in how often major news media feature books, articles, and information on the brain. As indicated by attendance at professional conference sessions on the brain and learning and sales of books on this topic, the brain also intrigues educators.

A Question of Brain Relevance in Education

This barrage of brain-related information offers valuable data on the structure and function of the brain. But, is this information relevant to educational practice? Some question the legitimacy of linking brain science to education. John T. Bruer, president of the James S. McDonnell Foundation, is one such individual. The span between brain science and education requires "a

bridge too far," he suggests. Bruer bases this judgment on the risk of inappropriate application of information. A little knowledge about a highly complex organ can easily be oversimplified or misused, especially in the current climate of eagerness and intrigue with the brain.

Others assume a different stance, however. They argue that of all professions, teachers shape brains more significantly than does any other profession. This shaping of the future, they contend, merits legitimacy for teachers to better understand the organ they purposefully influence. Accordingly, many books and much focus on translating neuroscience for educators now exist to guide teachers.

One example is the work of Case Western Reserve University's James Zull. In his book *The Art of Changing the Brain: Enriching the Practice of Teaching by Exploring the Biology of Learning*, Zull explains how neural plasticity—the brain's ability to change and grow with experience—is directly influenced by the quality of what goes on in the classroom. He illustrates how the dendrites of neuron cells in the brain show growth after just 15 minutes of cognitive stimulation. Zull links brain processing to learning theory and further substantiates the need for teachers to gain an understanding of the science of cognition.

A metaview such as Zull's aids in constructing a base of knowledge to promote appropriate applications of science to education. Yet, an inherent question merits consideration: Who determines which authors are reputable for providing guidance and relating this type of information to classroom practice?

The absence of brain science curricula in teacher education creates possibilities for "educational hucksters" to capitalize on this lack of knowledge, according to Robert Sylwester. Early in the emergence of educational brain science focus, Sylwester, one of the first university professors to provide teacher guidance in this area, drew attention to the need for scholarly focus on education-related brain science.

Citing previous vulnerability to "pseudoscientific fads, generalizations, and programs," such as right brain/left brain focus that exaggerated the conclusions of research findings, Sylwester cautioned against potential misuse of scientific data. Without sufficient training of teachers to prudently align brain science with classroom practice, he warned, the general public may become as well or better informed on this topic than are teachers themselves.

In spite of this and similar counsel, teacher education programs have not readily moved to include brain-relevant curricula in teacher training. A major reason for this is the lack of instructors trained to appropriately merge brain science with education. The next section describes progress toward this goal.

Historical Background

University of California, Berkeley

Marian Diamond, from the University of California, Berkeley (UCB), was one of the first pioneers in merging brain science with education. Though a teaching professor at UCB, Diamond is primarily a scientist—a world-renowned neuroanatomist—more than a trained educator. Even so, in the early 1980s at UCB's Lawrence Hall of Science, she and colleagues developed a massive interactive museum display on the brain to educate students and teachers. Busloads of children from California and beyond traveled to this site to learn more about the most complex entity in the universe—the human brain. To further extend this educational support, Diamond and Janet Hopson later wrote a book titled *Magic Trees of the Mind: How to Nurture Your Child's Intelligence, Creativity, and Healthy Emotions From Birth Through Adolescence.*

Association for Supervision and Curriculum Development

Influence of Diamond and others, along with technological advances in neuroscience, continued to make knowledge about the brain more comprehensible to the general public. Subsequently, both high interest in brain science and a perceived need to relate this new information to classroom practice provided impetus for new direction in professional development for education. The Association for Supervision and Curriculum Development (ASCD), a professional organization for teachers and school administrators, turned its attention to the brain and learning.

At ASCD conventions, sessions on education and the brain soared in popularity. In response, ASCD published related books. One of their first publications was Renate Caine and Geoffrey Caine's *Making Connections: Teaching and the Human Brain*, published in 1991. About 6 years later, another of ASCD's published books became a bestseller and remained so for many years—Eric Jensen's *Teaching With the Brain in Mind.* This book maintained a high profile of

popularity with K–12 teachers because it made information about the brain understandable for those with little background in neuroscience. Others, however, responded less enthusiastically to this book and drew attention to its lack of research references supporting claims and inferences. Still, this book played a seminal role in informing teachers about basic concepts of brain science and providing ideas for creating brain-friendly classrooms.

Learning Brain Expo

Keen to the urgency and need for more information for classroom practice, Jensen produced other books, provided intensive teacher training sessions, and organized professional conventions called *Learning Brain Expo*. These 4-day conferences in various locations throughout the United States and beyond continue to attract teachers' attention today. Featuring presentations by scholarly researchers as well as effective classroom practitioners, the conferences focus on classroom efficacy.

Harvard University's Graduate School of Education

About the same time Jensen's efforts gained popularity among educators, Harvard University's Graduate School of Education (HUGSE) began a program called *Mind, Brain and Education* (MBE). To extend the mission of this initiative, HUGSE invited key individuals—from national and international institutes of higher education—to meet at Harvard in groups of 70 for week-long sessions during the summer season. These interactive, collaborative meetings not only provided a certain degree of calibration for educator emphasis on brain science but also spawned a network of professionals to actively promote this focus in teacher training both in North America and abroad. This endeavor heavily emphasized a scholarly, theoretical, and research-based approach to education-related brain science.

Learning and the Brain Conferences

Carrying forward a scholarly emphasis, *Learning and the Brain* conferences developed as a joint venture between Public Information Resources, Inc., the Kosik Neurobiology Lab at Harvard Medical School (now at the University of California, Santa Barbara),

and the MBE program at HUGSE. These conferences feature a distinguished faculty of professors, neuroscientists, and researchers who offer dynamic perspectives on the brain and learning. This venture also provides member benefits in an organization called the *Learning and the Brain Society.*

Whereas the Jensen *Learning Brain Expos* tended to be located on the West Coast of the United States, the Harvard collaboration focused on East Coast offerings—in the Boston/Cambridge, Massachusetts, area or at the National Institutes of Health in the Washington, D.C., area. Currently, both of these conferences convene on both coasts of the United States and beyond.

International Mind, Brain and Education Society

Another professional society also spawned from this Harvard collaboration. Kurt Fischer and Marc Schwartz, along with others affiliated with the HUGSE's MBE program, formalized their affiliations by establishing the International Mind, Brain and Education Society (IMBES). Aimed at promoting research and scholarly dialogue, this organization offers a refereed journal and newsletter, book reviews, conferences, and other member benefits.

A metaview on brain-relevant education suggests that a tension exists between those whose main focus is research/psychology/learning theory and those who emphasize practical aspects of educational brain science. On the premise that disequilibration is vital in warding off rigidity and stasis—not just in biology, but in education as well—this tension between theory and practice provides benefit in promoting active dialogue and forward progress. The next section offers additional rationale for this perspective.

Philosophical Metaperspective

Many voices speak about the brain and learning—from macro- and micro-levels of interpretation and from holistic perspective. Philosophical tensions have much to do with what these voices say.

Macro-intersystemic voices tend to describe brain activity as a phenomenon of its environment. They speak of inferred brain activity based on observable evidence of brain activity in behavior and brain malfunction, movement, and language.

Metacognition and abstract analysis typify this perspective on the brain. Proponents of this perspective often describe the brain in cause-and-effect terms and metaphoric analogies such as computer hardware and software. Voices in this category tend to be those of cognitive psychologists, linguists, physical anthropologists, philosophers, artificial intelligence experts, and neuropsychologists.

On the other hand, *micro-intrasystemic voices* reflect on the brain by studying brain activity from within the human unit. They describe cells, molecules, amino acids, neurochemicals, and smaller cellular systems within more complex systems. This perspective focuses heavily on quantification or measurement of brain activity. Voices in this category tend to be those of neuroscientists, neuroanatomists, neurophysiologists, and neurochemists.

The graphic in Figure 1 depicts the educator's relationship to these two categories of specialists.

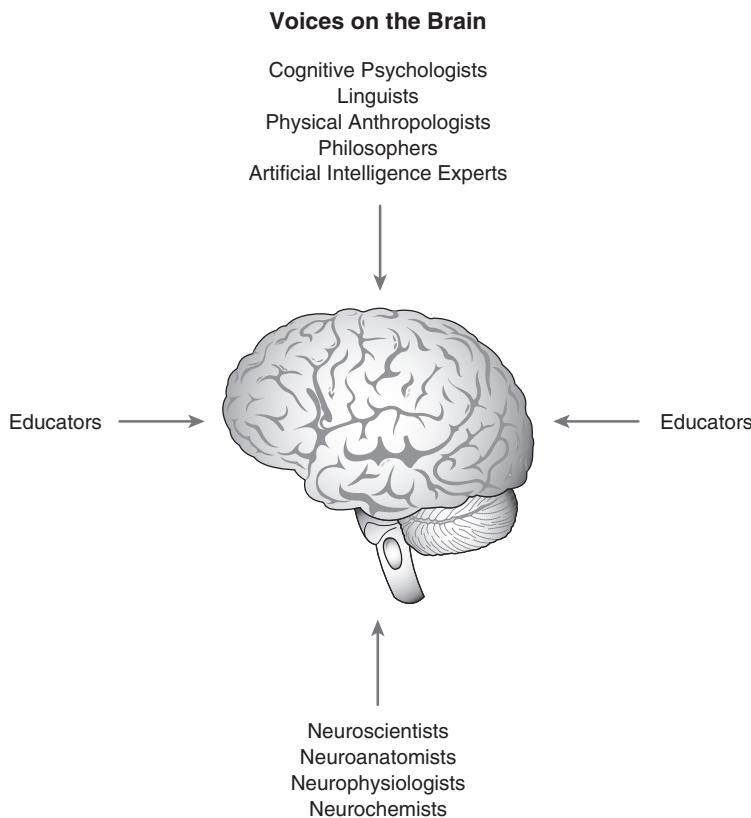

Figure 1   Voices on the Brain

Source: Copyright 2001 Linda Bryant Caviness. No duplication without permission.

Note: This graph depicts varying perspectives on the brain.

Typically, educators are not trained as specialists in behavioral or biological sciences. Yet, societal pressures call for more focus on the brain in education—or the science of education. To date, however, state and federal departments of education have not taken action to infuse teacher training with this burgeoning body of new information.

Reductionist Versus Constructivist

Added to this lack of professional training is another layer of involvement—one implied previously in regard to the tension between two foci: theory/ research and classroom practice. Much of the tension here results from two varying perspectives—one favoring a reduced, fragmented, controlled, linear, measurable emphasis and the other honoring a holistic, qualitative, naturally represented reality. Though seldom articulated, this tension is strong in the realm of education-related brain science.

A Newtonian–Cartesian mind-set—the philosophical perspective that tends to admit to reality only measurable evidence that has undergone the process of reductionistic examination—continues to be the heavyweight champion today in the sciences and in educational psychology and philosophy. The No Child Left Behind (NCLB) initiative demonstrates the strength of this influence. Before NCLB, constructivist processing and learning commanded a respectable position in bureaucratic function. However, NCLB quickly returned the pendulum's swing to a more controlled and quantitative position on assessment and instruction.

This position promotes the value of direct instruction and controlled curricula, as opposed to nurturing creativity and allowing the student to share the role of the teacher and to be in charge of his or her own learning at least some of the time. According to Zull, movement is cognition expressed, and that movement is most meaningful cognitively when it stems from intrinsic drive—a personal desire from within to learn.

Proponents of brain-relevant education recognize the value of both quantitative and qualitative perspectives in research to

better understand the brain and learning. They value behaviorist and constructivist contexts. Too much weight on either of these dualistic positions diminishes valuable tension that prevents debilitating stasis. This same need for equalized tension represents itself in the following relationships with regard to the brain and learning:

- Nature Versus Nurture
- Passive Reflection Versus Active Processing
- Extrinsic Drive Versus Intrinsic Motivation
- Concrete Thought Versus Abstract Thought
- Skills Versus Creativity
- Objectivity Versus Subjectivity
- Control Versus Freedom
- Specialization Versus Holism

Education-Related Brain Science Themes

A conclusive finding in the study of the brain reveals that the brain functions symbiotically. Linear processing certainly occurs throughout the brain, but many of these linear processes happen simultaneously. Interconnectivity defines brain function.

This principle reveals itself in themes surfacing in brain-relevant education. These emerging themes suggest that learning is best facilitated with holistic nurture that equally honors mental, physical, and emotional/social/spiritual stimulation. These themes include, but are not limited to, the following:

Body and Mind. Body and mind are integrally related in all life processes, including the ability to learn, and the heart is surfacing as a significant player in this dynamic relationship.

Senses. Learning is a multisensorial, integrated process, which involves the body and brain, not just the brain alone.

Exercise and Movement. Physical exercise and movement empower learning by promoting oxygen exchange and vitalization of various physiological processes.

Health Habits. Health habits (nutrition, fresh air, sunshine, exercise, water intake, rest, low stress levels, moderation, and regularity) profoundly influence the brain, its development, and its ability to learn.

Emotions and Neurochemistry. Emotions and neurochemistry facilitate and transact mental processes and bodily functions as they aid information transfer and create mental states through repetitious disequilibrations—moving from balance to imbalance repeatedly by means of electrochemical exchange.

Music and the Arts. Music and the arts facilitate brain development and maintenance through highly integrative stimulation.

Attention. The brain's attention—how it is gained and maintained—is driven by sensorial intake, physiological factors, levels of motivation, memories, and degree of novelty perceived in relation to prior knowledge.

Social Influences. Sensory input from community and environment promotes brain development and stimulates the expression of genetic proclivity.

Plasticity and Enrichment. Areas of the brain are plastic and capable of changing or growing with varying levels of nurture and environmental influence.

Stages of Development. Brain development stages create optimal times—often referred to as critical periods—for particular learning opportunities.

Language. Language shapes the brain, thinking, and culture.

Making Meaning. Learning involves making connections within complex neural and chemical networks, and relating new knowledge to prior knowledge is how the brain constructs meaning.

Individualism. The learner is a complex, unique individual, and each brain is uniquely different and functional.

Motivation. When intrinsic motivation drives the learner, the brain can and does create its own rewards; however, though extrinsic motivation tends to promote skills development, it can lessen creativity if the brain is not allowed also to be in charge of its own learning.

Memory. Rather than being a discrete, singular skill in a particular area of the brain, memory is a process subject to constant neurochemical change as a result of changing stimuli and emotional states; furthermore, memory can develop in various locations and organs within the brain and body.

Theme Connectivity

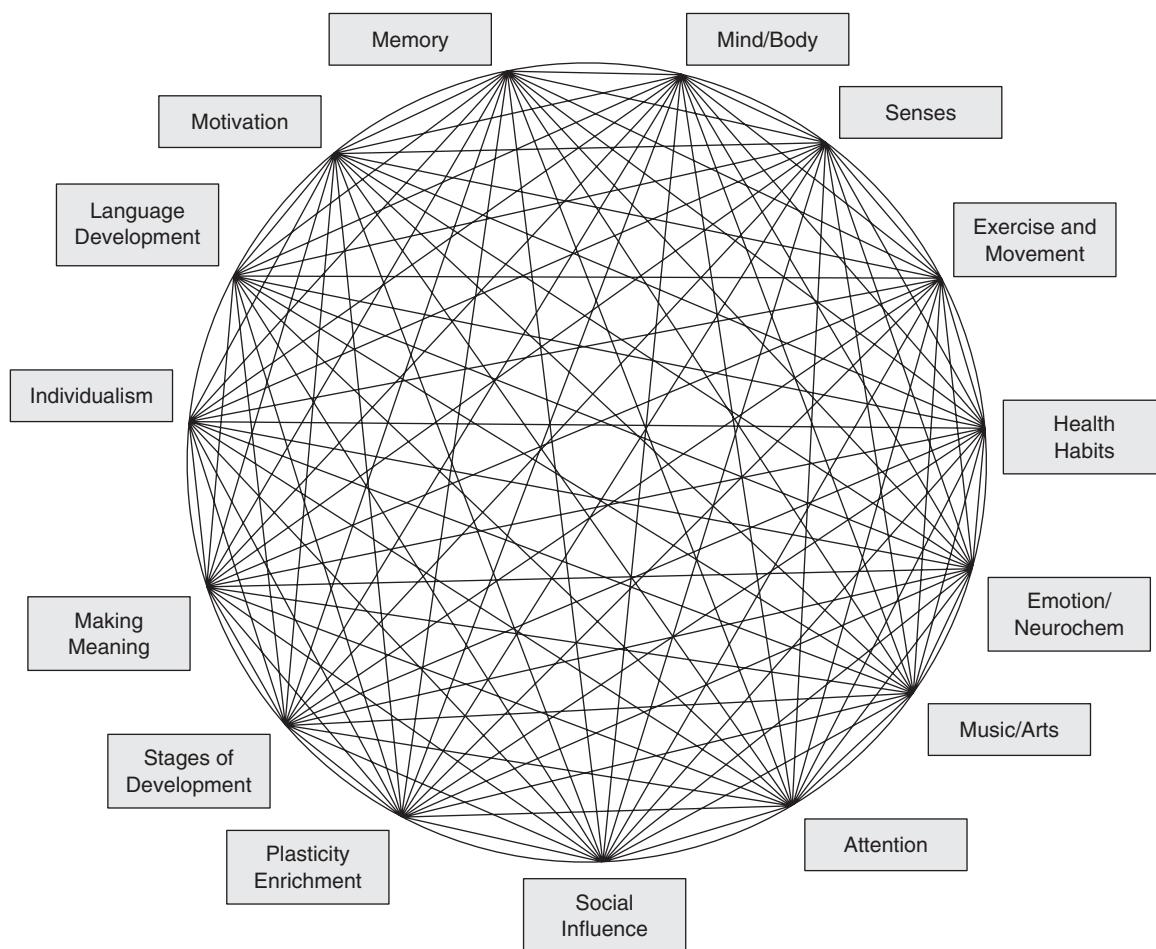
Figure 2 illustrates further the symbiotic nature of brain function as mentioned previously. Placing each of the themes (listed previously) around the exterior of a circle and drawing lines from each theme to other connected themes demonstrates


Figure 2   Theme Connectivity

integral connectivity—much like the dynamic connectivity now known to exist among cells, systems, and subsystems of the brain itself. This interrelatedness may provide insight for better understanding of the importance of creating multidisciplinary and integrated learning environments.

Holistic Brain Nurture

Throughout much of the professional literature on brain-relevant education, writers reiterate a major concept: The brain thrives with nurture that honors balance among mental, physical, and social/emotional/spiritual stimulation. Linda Bryant Caviness postulates that this triad emphasis of mental, physical, and spiritual function actually defines the structure and physiological

operation of the brain and body and its constituent parts in fractal-like fashion. Mental, physical, and spiritual functions together constitute a whole. To separate out one aspect of the human wholeness as more important than others disregards the integrity that defines the human brain and distinguishes it above other animal forms.

Traditionally, however, education has favored emphasis on mental nurture. Schools and school systems often cut physical education and the arts first when budgets undergo cost reduction. Though education often claims to honor holistic mental, physical, and spiritual nurturing, in actuality a philosophical perspective that favors reduced, fragmented, linear conceptualization drives the decisions that shape pedagogical practice. Brain-relevant education exposes this dualistic reality.

The science of heart–brain connections now contributes to brain-relevant education. This research reveals an intimate relationship between heart and brain. Now described as a sensory organ with a little brain of its own, the heart significantly influences the quality of cognition. Recognizing the need to better understand this dynamic relationship, Ohio's Cleveland Clinic recently received $17.3 million to establish the Earl and Doris Bakken Heart-Brain Research Institute. These new data further contribute to the importance of education that is holistic.

Brain-Friendly Teaching and Learning

Howard Gardner's multiple intelligences, Daniel Goleman's emotional intelligence, Mihalyi Csikszentmihalyi's flow concept, and others all contribute to current knowledge about teaching and learning. Educators in the classroom, however, seek a particular model or schema to guide them while under the pressure of classroom practice. They desire a plan that combines the advantages of multiple learning theories as well as the knowledge gained from study of the brain.

One model that closely matches these expectations is Bernice McCarthy's 4MAT model for teaching and learning. This easy-to-remember plan is designed to honor three major tensions: active and passive processing, concrete and abstract conceptualization, and extrinsic and intrinsic motivation. Four major steps help teachers hold themselves accountable in respecting brain-friendly learning.

Step 1 helps students connect with prior knowledge and to examine what they already know or don't know. Here, the teacher engages student interest by fostering curiosity.

Step 2 provides opportunity for teachers to model and define the new concept didactically. Visual aids, demonstrations, and textual exposure help to introduce this content.

Step 3 allows students to physically experiment with the new concept under teacher guidance. This prevents internalization of erroneous information. This step also provides time for students to begin to extend the new concept to their own context.

Step 4 encourages students to refine their extended application through peer feedback before they teach their creative extension to others. As teachers swap roles with the students, they can easily determine how well students internalized the new concept.

McCarthy's model aligns well with Zull's explanation of how information is processed throughout the brain. Sensory data travel from brain stem to limbic area and on to the cortex. In the cortex of the brain, where conscious thought or higher order thinking takes place, information moves from sensory integration to conceptual integration and finally to motor integration. Similarly, McCarthy's model connects with the student's context socially/emotionally/spiritually, then promotes new conceptualization, and finally involves the student physically and creatively in real-life applications.

Knowledge about teaching and learning continues to develop. Brain-relevant education has only begun to add to the base of knowledge accumulated over many years of focus on behavior. In good faith it will continue to expand our understanding of human potential and the challenge of its nurture.

BULLYING

Bullying can be defined as consistent, purposeful negative behavior that is directed toward another individual or the persistent abuse of power, which is perpetrated by children and adolescents against their more vulnerable peers. It can take many forms including physical, verbal, and social aggression and is a prevalent part of school life that can have serious, detrimental effects on those who are involved. It can also occur among adults in workplace settings. Although girls and boys are equally likely to be involved in bullying, girls are more likely than boys to use social aggression. Bullies themselves are often quick tempered and may target their victims simply for fun or because they often have many witnesses, including teachers, and can gain a great deal of status from engaging in this type of behavior. This implicit sanctioning of bullying helps to create an unsafe environment. Intervention and prevention programs that are targeted at the whole school are considered to be the most effective in reducing levels of bullying.

Bullying includes physical aggression (e.g., hitting, kicking, and aggressive gestures) and verbal aggression (e.g., threats, insults, and mocking). Other forms of social manipulation that are directed at undermining the individual's social standing (e.g., spreading distasteful rumors) can also constitute a form of bullying.

Bullying is distinguished from more general aggression by the nature of the relationship between the bully (also referred to as the perpetrator) and the target (also referred to as the victim). In this relationship, the bully is usually seen as a more powerful individual or as part of a more powerful group. The victim, in contrast, is usually seen as weaker or different and hence vulnerable. Power and vulnerability in this context does not necessarily refer to physical strength but can refer to a number of physical and personal attributes.

Bullying has most often been studied and considered within the school context, although recently there has been interest in workplace bullying. Thus, the issue of bullying is relevant to educational psychologists working in school and vocational settings. In the school context, the educational psychologist has the responsibility of ensuring that children are safe at school and that bullying behavior is detected, reduced, and prevented. Ensuring the safety of children and young adults is important not only from a legal standpoint but also from a humanist standpoint. According to Abraham Maslow, two of our basic human needs are safety and a sense of belonging or connection. If an individual is threatened by a bully, then his or her sense of safety can be undermined. Furthermore, victims of bullying are unlikely to feel connected to their school, classroom, or peers. Without this sense of belonging or connection, victims of bullying will have difficulty focusing their attention on learning.

The educational psychologist can work with colleagues to ensure all personnel and students are aware that bullying is unacceptable and are able to identify and report instances of bullying. Part of the role of the educational psychologist is to ensure a school climate in which bullying is not acceptable. When bullying has been detected or reported, the educational psychologist can design interventions to stop bullying by intervening directly on the behavior of both the bully and victim. Strategies to prevent bullying can also be designed and implemented at the whole school level.

A similar array of bullying behaviors that are seen in schools and vocational settings are also found in the workplace. However, workplace bullying often is more subtle than the overt acts of aggression observed in schools. For educational psychologists who are working with organizations, a similar set of principles should underpin their ability to intervene and prevent this sort of behavior; a detailed account of workplace bullying is beyond the scope of this entry, however.

It is important to distinguish bullying from other types of negative or aggressive behavior that is directed toward others. In addition to the power imbalance, bullying, by definition, refers to behaviors that are intentional, are persistent, and may involve an accumulation of incidents. Although violent or hostile behavior is similar to bullying, it can be a one-time event, and the

victims may be randomly chosen. Bullying, in contrast, is characterized by a persistent pattern of ongoing negative behavior directed at one or more specific targets or victims.

Harassment and *teasing* are other terms that are related to bullying. The former is often used with reference to sexual harassment; similar to other bullying behavior, harassment frequently is an ongoing behavior acted out against a particular target. When referring to the school context, sexual harassment can be subsumed under the heading of gender-based bullying. Teasing refers to a broad range of behaviors. At one end of the spectrum, teasing can be light-hearted banter between friends; however, the nature of the relationship between the individuals usually distinguishes teasing from bullying. If there is a clear power differential, the line between teasing and bullying can become unclear, especially when the teasing is persistent, one-way, and akin to mockery.

Forms of Bullying

The most obvious forms of bullying behavior are those that involve physical aggression, which may be minor or may lead to severe physical injuries or disfigurement. As with any sustained assault, bullying may result in psychological trauma for the victim. Other forms of bullying behavior may be verbal in nature and can include name-calling, threats of physical aggression, and hostile teasing. Similar to physical bullying, verbal bullying also has the potential to have a negative psychological impact on the victim. The final category of bullying behavior includes more indirect forms that are designed to socially exclude the victim or damage the individual's social standing by changing the peer group's perception of the victim. These forms of behavior may be overt and include negative body language such as turning away, staring, and eye rolling. They may also include verbal or written comments that ostracize the individual from his or her social world. This destructive social behavior can include the manipulating friendship groups, publicly sharing confidential information, or spreading unpleasant rumors so that the individual is socially excluded from his or her peers. Some aspects of this later form of social aggression have also been referred to as *relational aggression.*

It is important to note that often an individual may be subjected to both overt and covert forms of bullying, and the lines between the two types can become blurred, particularly when the behavior is not physical. Furthermore, if the bullying is covert, the perpetrator may remain unknown to the victim; this situation can result in further psychological trauma for the victim.

Bullying in Context

Physical and verbal bullying behavior can occur on the playground, lunchroom, before and after school (e.g., on the bus or near the school entrance), at school camps, or during school excursions. For high school students, the bullying may occur in hallways during the transition between classes. Although bullying usually occurs out of the teacher's sight, more subtle but direct behaviors may occur within classrooms in front of teachers. These behaviors may include social exclusion and the use of negative body language or other comments and actions. In the presence of the teacher some of these may be disguised as "teasing" or as "an accident" (e.g., tripping an individual, leaving something unpleasant on a child's seat).

Over the past decade, the nature of bullying has begun to change with the increased use of technology. For example, computers and the use of the Internet are a common part of school life in most developed countries. The use of Internet connections at home and the increased use of mobile phones by children and adolescents (including text-messaging) have resulted in targets being more accessible to bullies virtually 24 hours a day, 7 days a week. Not only are victims more accessible now, but the perpetrators are better able to remain anonymous. Whereas traditionally an anonymous note or phone call would have been the only option, perpetrators are now able to use text messages and unidentifiable e-mail addresses to ensure their anonymity.

Children Who Are Bullied

Victims of bullying are often cautious children who appear vulnerable, anxious, and lacking in confidence. Children also may be targeted simply because they are new to a school or neighborhood, have few friends, and are not obviously a part of any social group. In addition, children may be targeted for any number of seemingly innocuous reasons. For example, they may be wearing the wrong clothes, be overweight, seem weak, or be too tall or too short. Bullies may also focus on an individual's religious affiliation, ethnicity, race, or socioeconomic status. Individuals may also be

bullied because of their sexual orientation. However, there is some evidence to suggest that the cultural and social context will have a significant impact on the relative prevalence of bullying based on these factors. Whether the abuse is directed at a particular individual or not, oftentimes the climate or atmosphere of hostility toward individuals who are GLBT (i.e., gay, lesbian, bisexual, or transgendered) is likely to be apparent within a class or school context because derogatory terms can permeate the classroom language.

Gender-based bullying refers to bullying behavior that is targeted toward an individual because of his or her gender. Although this type of bullying has been common in coeducational schools for some time, it is only recently been considered as a form of bullying. It can be directed at either girls or boys and may be related to any aspect of the individual's appearance, interests, or behaviors that are counter to sex-role expectations. For example, if a girl has a very short haircut or if a boy wears a pastel shirt, each may become a target of gender-based bullying. Also, if a boy shows an interest in a nontraditional occupation, such as dance, or a girl wants to participate in football, each may be bullied about his or her choice. When the bullying behavior has distinctive sexual overtones, it is likely to be classified as a form of sexual harassment. Although this type of bullying can occur to both boys and girls at any stage of their development, it is more likely to occur in adolescence and to girls who have reached puberty earlier than their peers.

Another group of individuals who may be targeted for bullying behavior are those who have some form of disability, whether it is a physical disability, learning difficulty, intellectual disability, or social or emotional disorder. Although the mainstreaming of all individuals with disabilities has had many positive outcomes and is considered, in most circumstances, to be best practice, there have also been some costs. In particular, individuals with disabilities may become targets for bullying, particularly if the school or classroom teacher has not engaged in any diversity training or instruction. For some individuals, particularly those who have intellectual disabilities, not only is their ability to defend themselves limited but they are also less likely to have any allies within the school.

According to a report commissioned by the American Medical Association, some of the strategies victims employ to cope with the bullying include enduring the bullying, reporting the incident to school personnel or a family member, seeking revenge, retaliating, finding allies, or ignoring the bullying. Often, however, the bullying goes unreported; less than a quarter of bullying incidents are reported to an adult, according to the American Medical Association.

Identifying Bullies

Although not all children engage in bullying behavior, the typical bully is not easily distinguishable from peers. That is, boys and girls from all socioeconomic backgrounds, religious affiliations, cultures, sexual orientations, and abilities have the potential to engage in bullying behavior at some point in their lives. However, according to a report written by Dan Olweus and colleagues, it appears that there are a number of individual, peer, family, school, and community factors that contribute to the likelihood that a person will engage in bullying behaviors. In particular, children who are easily angered, are impulsive, view violence in a positive way, and have low levels of empathy toward others are at risk for bullying. Other risk factors include low levels of parental warmth, permissive parenting, and harsh discipline. Within the school environment, peers can play a significant role if they have similar views to the child with regard to the acceptance of violence. Furthermore, a school culture that accepts bullying and fails to closely monitor children's behavior can also be a contributing factor. It is the interaction of these factors that puts a child at risk for engaging in bullying behavior.

There is also evidence to suggest that some individuals may engage in the behavior because they lack social skills. Their social inadequacy results in an inability to form appropriate relationships with the peer group. This deficit in effective social communication can have numerous causes, including modeling from the home environment, where they may witness bullying behavior between siblings or parental figures. However, the social skills deficit model has been questioned because bullies who engage in social aggression appear to have fairly sophisticated understandings of social behavior. Thus, it appears that a lack of social skills may be associated with some but not all bullies.

Contrary to popular belief, bullies are not necessarily social outcasts; in fact, most have friends at school and are very much a part of their peer group. They often have a healthy self-esteem and can at times be part of the "popular" crowd. Although this seems somewhat counterintuitive, given that popular children have traditionally been considered friendly,

cooperative, and well liked, recent research in the field of peer relations has highlighted that there is a subset of popular individuals who are "popular but not well liked." That is, other members of the peer group may hold these popular individuals in high regard, but they also may recognize that these individuals may be very socially aggressive so they do not necessarily make desirable friends. For a small subset of bullies, the cycle of victimization is continuous because they are also victims of bullying. These bully-victims are often quick tempered and try to retaliate in a violent way and may then, in turn, bully younger or weaker children. Similar to victims, bully-victims are also at a high risk for internalizing disorders such as anxiety and depression.

Reasons for Bullying

According to Ken Rigby there have been numerous reasons put forth as to why some children and adolescents engage in bullying behavior, including for fun, for revenge, or because of peer group pressure. The notion that bullying behavior is enjoyable has some support in operant theory, which suggests that bullies engage in this behavior because it is rewarding. The behavior might also be shaped and maintained because of the consequences of bullying. That is, bullies are positively reinforced for their behavior because they find it enjoyable or they are able to gain tangible objects (e.g., money, food, or other desirable items the target may be forced to relinquish). Furthermore, bullies may gain positive reinforcement in the form of attention from their peers, with the possible increase in status within the peer group. It is also possible that bullies may receive some personal satisfaction in intimidating another individual, as it makes them feel more powerful, particularly if they feel powerless or inadequate in other areas of their school or home life. Thus, bullies may engage in the behavior to alleviate boredom, to entertain themselves, or to distract themselves from the more serious and difficult task of schoolwork.

The notion that some children bully because of peer pressure or to entertain their peers highlights that bystanders or witnesses can play a significant part in bullying. Witnesses fall into a number of categories of involvement, including those who (a) do not instigate, but still take part in the bullying, (b) encourage the behavior, (c) passively watch, or (d) overtly discourage it or report the incident to adults. Whatever their involvement, passive witnesses play a vital role,

as they make up the majority of the school environment. By failing to stand up for or defend a victim, peer witnesses are implicitly condoning the behavior and reinforcing the normality of the situation as well as implying that it is somehow the victim's fault. The same applies for adult witnesses who may unwittingly overlook bullying behavior or consider it to be a natural part of growing up and thereby provide tacit support to the bullies.

Consequences of Bullying

Although there is some evidence to suggest that not all children who are victimized suffer long-term effects of their experiences, those who are affected, either as bullies or as victims of bullying, can suffer significant repercussions with regard to their learning outcomes, health, and socioemotional well-being. For example, victims may suffer from low self-esteem, loneliness, anxiety, and/or depression, all of which may influence their immunity to illnesses. Victims are more likely to suffer from stomachaches, headaches, and suicide ideation; in extreme cases they may engage in self-harm or suicide.

When victims' mental health is compromised it can have a significant influence on other aspects of schooling, including their relations with peers, academic performance, and their willingness to engage in extracurricular activities. Victims are unlikely to feel safe, and because they need a strong sense of security to prosper at school, they may disengage from school. In addition, victims may not have the coping skills or social networks to defend themselves, which increases their vulnerability. Victims of bullying may also engage in externalizing behaviors, such as overt aggression, or other risk-taking behaviors, such as increased drug and alcohol consumption. There are also consequences of bullying for the bullies themselves. They are at increased risk for dropping out of school and are more likely to engage in criminal activities as young adults.

Prevalence of Bullying

To determine the extent to which bullying occurs in schools, a range of different measurement procedures have been developed, including teacher reports, peer nominations, phone-ins, interviews, and direct observations. The most commonly used measure of bullying prevalence is through self-reports, which is the method used in the pioneering work of Dan Olweus

and his colleagues in Scandinavia in the 1970s. Olweus's large-scale studies of 150,000 schoolchildren in Grades 1 through 9 found that 15% of children reported being victims of bullying several times during the previous 3- to 5-month period.

It appears that little has changed in the intervening years with similar levels of victimization found in countries such as the United States where a number of surveys have found bullying rates hovering around 20%. However, there appears to be a developmental progression both in the types of bullying used by children and adolescents and in the prevalence of bullying. Overall, the most frequently used form of bullying for all children is verbal bullying. Children become less physical as they get older and begin to engage in more verbal and social forms of bullying. In addition, there is a fairly consistent decrease in the amount of bullying children experience (or at least report) through the elementary grades. According to a report by Tonja Nansel and her colleagues, bullying rates appear to drop from 25% to 10% between the sixth and tenth grades. However, there is evidence to suggest that a resurgence of reported bullying incidents occurs around times of transition, such as when children are moving from elementary to secondary school, where they are once again the youngest and smallest members of the peer group.

Gender and Bullying

Although boys and girls are just as likely to engage in bullying, some differences have been identified in terms of the types and frequency of bullying. In particular, boys tend to bully more frequently than girls, and boys are more likely to engage in physical and verbal bullying behavior than are girls. Girls, in contrast, are more likely than boys to engage in social bullying. In terms of victimization there are conflicting findings, with some studies showing that girls and boys are victimized at similar rates and others suggesting boys are victimized more often than girls. With regard to the targets of bullying, boys tend to bully both girls and boys, whereas boys are usually victimized only by other boys.

Intervention and Prevention

For many years bullying was considered by some adults to be just a natural part of growing up and something that children and adolescents had to

endure. However, over recent decades a sufficient number of international reports highlighting the potential effects of bullying on individuals' mental health—including the risk of suicide—have altered this prevailing attitude. Today there is more recognition of the need to prevent and reduce bullying. To intervene and ideally prevent bullying from occurring, adults in schools need to be acutely aware of the myriad forms of bullying. The accurate identification of bullying has therefore been an important issue for educators and school psychologists. It appears that adults in schools tend to overestimate their ability to intervene and address bullying. Studies have shown marked differences between students' and teachers' perceptions of the effectiveness of adult interventions.

Traditionally, the intervention strategy of choice was to target the bully for punishment or rehabilitation; however, this has been found to be an ineffective method that can backfire on the victim because the perpetrator may retaliate against the victim for reporting the incident. One attempt at rehabilitation is to bring the perpetrators together to talk about their behavior and to teach them alternatives to aggressive behavior. However, the net effect is bullies may gain some sense of power from this acknowledgment and may also learn new bullying techniques from their peers. Along similar lines, the victim has been targeted for remedial work in the area of social skills and coping strategies. Again, this approach alone is usually insufficient to alleviate the problem because it inadvertently places the blame on the victim.

When school systems, policies, and procedures are not cognizant of the detrimental effects of bullying, it is unlikely that the staff and students will take prevention and intervention seriously. Therefore, the most successful methods of prevention and intervention are those based on a comprehensive whole-school approach first proposed by Dan Olweus and colleagues. The Bullying Prevention Program has been used across hundreds of schools worldwide and has proven to be effective in reducing bullying. The basic premise of the program is that bullying behavior has its roots in the culture of the school, and if educators and parents believe that children have a basic human right to feel safe at school, then the school has a responsibility to create that safe environment. This whole-school approach requires a systematic commitment to changing the prevailing culture; to do so, it is necessary to intervene at all levels in school by including the

individual children, classmates, teachers, administration, and parents in all aspects of the program.

Calculator Use

Computers, four-function calculators, and graphing calculators have assisted in the development of significant advances in the field of mathematics. For example, the famous 4-color theorem went unsolved for more than 100 years until 1976, when the calculation and visualization powers of computers were utilized to derive a mathematical proof. Advances in production speed, manipulation, and representation of data through the use of calculators and computers have also benefited the field of statistics, including the specific area of educational statistics. Educational psychology has taken advantage of these advancements in product technologies to support research and theory in the field, particularly in regard to these technologies' abilities to support statistical computation and manipulation.

Although the first desktop calculators were available in the 1960s, their commercial availability did not emerge until the early 1970s. These early "four-function" calculators were limited in scope in that they were able to perform only the basic mathematical operations of addition, subtraction, multiplication, and division. In the late 1970s, companies such as Casio, Hewlett-Packard, Sharp, and Texas Instruments began to produce programmable calculators. These models had small memory chips capable of storing a limited number of preprogrammed algorithms, including square root, exponents, and basic statistics. Some of these models also allowed users to input basic computer code and program their own algorithms.

In the early 1990s, graphing calculators greatly expanded the user capabilities of the handheld devices. The ability to compute fixed algorithms, represent functions and data in multiple ways, and support simple computer codes, made the graphing calculator a prime example of a product technology that allows for an enormous amount of mathematical power, speed, and visual representation. Graphing calculators readily support the production and use of educational statistics through the calculation of statistical tools such as mean, standard deviation, and quartiles, allowing researchers an efficient and thorough view of quantitative data. However, educational psychologists have extended the power of calculators beyond the computing of statistics. Graphing calculators can support statistical research through plotting two-variable statistics; looking for patterns in two-variable situations to determine an underlying model to interpolate or extrapolate; and conducting various hypothesis-testing procedures, including *t*-tests, regressions, and analysis of variance (ANOVA).

To illustrate, let us suppose an instructor believes that attendance is an important factor in student motivation. A survey is given at the beginning of the course to determine beginning motivation levels (0–100 scale). The data are gathered, organized into

a list, and entered into the calculator. Various statistics can be quickly produced, including mean, standard deviation, and quartile boundary values. These numbers provide a clear picture of students' self-perception of motivation levels at the beginning of the course. In Figure 1, the middle column shows the mean (55.96) and standard deviation (14.87), whereas the right-hand column shows the five quartile values, including the minimum (20), median (58), and maximum (77).

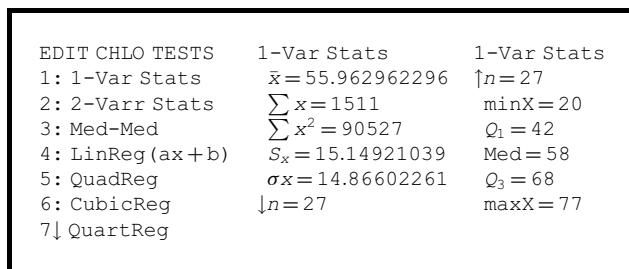
4: LinReg(ax+b)    Sₓ=15.14921039     Med=58
5: QuadReg         σx=14.86602261     Q₃=68
6: CubicReg        ↓n=27              maxX=77
7↓ QuartReg
```


Figure 1   Students' Self-Perception of Motivation Levels at the Beginning of the Course

Although a four-function calculator could also produce these statistics, users would need to know the algorithms for computing the statistics, and input the quantities and operations in a lengthy, step-by-step process for each one. The built-in algorithms available in graphing calculators (or any calculator with these preprogrammed functions) allow users to produce these statistics quite easily.

Let us further suppose that, throughout the course, instructors implement the curriculum and record the students' attendance. Student motivation is measured again at the end of the course, and a new set of data is gathered and organized into another list. Changes in beginning and ending motivation levels could then be computed quickly for each student, creating a third list.

After entering the days present in class for each student into a fourth list, the instructor can then graph a scatterplot with days present as the independent variable and change in motivation as the dependent variable. With an appropriate viewing window, instructors can see a graph of the scatterplot (see Figure 2). Instructors can look at residuals to see if the model chosen is the most appropriate (see Figure 3).

Once the most appropriate model is determined, instructors can use it to predict attendance based on motivation levels. This can be very helpful in designing interventions for both student attendance and motivation.

In the past 10 years, there has been relatively little growth in the functional capacity of handheld calculators. Instead, a variety of communication, data storage, and photographic technologies have emerged as the choice of users of advanced handheld tools. Educational psychologists should look to the future to see how the functional capacities of current calculators will be incorporated into these emerging devices, and the degree to which these new devices will have an impact on the field.

CASE STUDIES

There are many different ways to study scientific phenomena, and one of the defining factors is whether the phenomenon, be it an individual (such as a child in the third grade) or an institution (such as a corporation), is studied in groups or individually.

The case study approach is a method used to study an individual, an institution, or any unique unit in a setting in as intense and as detailed a manner as possible. The word *unique* here is critical because the researcher is as interested in the existing conditions surrounding the object of study as much as the object of focus itself. In other words, if one were to study an 8-year-old child with a focus on her social development, one would, of course, spend a great deal of time on the child's psychological, emotional, and physical well-being, but also on her school relationships and the dynamics of her family. Similarly, one would not study the XYZ Widget Company by looking only at its profit-and-loss statement, but also looking at employee relations, policies, and other practices as well.

Many readers may have heard the term *case study* used before. The idea represents a major part of the methodology that physicians use to collect and disseminate information. The *Journal of the American Medical Association*, or *JAMA* (published weekly by the American Medical Association), regularly offers case studies of individuals whose conditions are so unusual that their symptoms and treatment demand special attention, and information about their cases needs to be disseminated. Also, the Harvard Business School regularly uses the case study model in its curriculum.

Physician-turned-psychologist Sigmund Freud pioneered the use of the case study in the development of his psychoanalytic theory. His famous patient, Anna O., and his detailed observations about her condition led to the use of free association as a method in the treatment of hysteria and other conditions. Also notable is the work of Jean Marc Itard, one of the first "special educators," and his case study description of the wild boy of Aveyron, which was the basis for the popular movie *The Wild Child.*

Advantages of the Case Study

Case studies offer several advantages over group studies of behavior, be it of an individual or an institution.

First, case studies focus on only one individual or one thing (for example, a person or a school district), and this allows close examination and the collection of a great deal of detailed data that can be further analyzed. Case studies are often used in a clinical teaching setting because of this advantage.

Second, because case studies encourage the use of several different techniques, a more varied collection of information becomes available. For example, personal observations, interviews, and other techniques all shed light on the focus of the study.

Third, there is simply no way to get a richer account of what is occurring than through a case study, which is what Freud did in his early work. He certainly could not have used a questionnaire to inquire about his patients' dreams, nor could he think to reach his level of analysis through the use of anything other than intensive scrutiny of the most seemingly minor details concerning the way the mind functions. These data helped contribute to his extraordinary insight into the functioning of the human mind and the first accepted stage theory of human development.

Fourth, case studies do not necessarily result in hypotheses being tested, but they do suggest directions for further study.

Disadvantages of the Case Study

Although a major tool in the qualitative methods kit, case studies do have shortcomings.

First, by their nature, they are limited in their generalizability. Studying one thing of anything does not easily apply to other, similar cases, be they individuals or institutions. The whole notion of a case study is to focus on the individual—by definition, indicating that individuals differ greatly from one another.

Second, although the case study model might appear to be easy to do (only one subject, one school, etc.), it turns out that this methodology is one of the most time-consuming research methods. Data have to be collected in a wide variety of settings and sources, and under a wide variety of conditions, and rarely is the choice available as to these settings and conditions.

Third, data may accurately reflect what is observed, but it is only one reality. Everyone comes to a given situation with a bias, and researchers must try not to let that bias interfere with the data collection and interpretation processes. The conclusions that are drawn based on case study science are based on a biased view of what is happening.

Fourth, what case studies provide in depth, they lose in breadth. Although they are extremely focused, they are not nearly as comprehensive as other research methods. As a result, case studies are appropriate only if one wants to complete an in-depth study of one type of phenomenon.

Finally, case studies do not at all lend themselves to establishing any cause-and-effect links between what is seen and the result. Although one can speculate, there is nothing in the case study approach that allows such conclusions to be reached.

Case studies do, however, reveal a diversity and richness of human behavior that is simply not accessible through any other method, but they have some serious shortcomings that have to be considered in investigations that scientists pursue.

CERTIFICATION

In the world of education, certification generally refers to the educational process by which future teachers earn the required state credentials to (a) teach specific subjects, (b) teach in specific areas, (c) teach specific grade levels, or (d) perform educational administrative functions in that state. This required teaching credential is often referred to as a teaching license or a teaching certificate depending on the term used by the department of education of the state granting the credential. Just as a driver's license can be categorized by the type of vehicle one is permitted to operate, so too, does a teaching license or teaching certificate specify what may be taught by the holder. Some certifications provide a license to teach specific subjects such as math, science, French, English, and so on, or to teach in specific grade levels or areas such as preschool, elementary (usually kindergarten to Grade 6), or special education, which can cover all grade levels and/or a specific need such as hearing impaired, gifted, and so on. There are also separate certificates for administration positions. Some of these are principal, curriculum supervisor, guidance counselor, or reading specialist. It is assumed that the holders of the teaching or administration certificates have met certain requirements that enable them to perform with knowledge and success in the specified domain.

Teacher Certification in the United States

In the United States, the responsibility for granting beginning teachers their licenses or certificates is borne by the state departments of education. Each of the 50 states has its own guidelines and qualification standards that must be met before a person is deemed certified to walk into a classroom to teach children. These state certification guidelines must be instituted by any university or college (private or public) that has a teacher education program within the specified state.

Because these guidelines are created independently by each state, there is often little consistency among the states' requirements. For example, in 2000, according to *Education Week*, 39 states required candidates for teacher certification to pass a basic skills test, but most of those states (36) had some sort of legal loophole that permitted some of the people who fail the exam to teach with a type of emergency or alternative certification. *Quality Counts 2000*, an annual 50-state report by *Education Week*, reported on teacher certification differences by stating that as a result of loopholes in state requirements, "millions of students sit down every day before instructors who do not meet the minimum requirements their states say they should have to teach in a public school" (p. 8).

An attempt to address this apparent lack of uniformity in qualifications for some teachers came with the passage of the No Child Left Behind (NCLB) Act of 2001, which was signed into law in January 2002. One portion of the 670-page NCLB Act of 2001 deals with "highly qualified teachers." This stipulation that each state must ensure that every public school elementary and secondary teacher is "highly qualified" before stepping in front of a classroom is a prime component driving certification standards. Highly qualified teacher requirements of NCLB are listed as a bachelor's degree, state certification, and demonstrated competency (as defined by the state) in each core subject that the teacher will be teaching. Many states are relying on standardized testing such as the PRAXIS™ series of tests to meet the "demonstrated competency" in each core subject. For many states, passing scores on various forms of the PRAXIS™ test in the core academic subjects that certification candidates intend to teach are required before certification is granted. Special education teachers and those who teach English-language learners must also demonstrate competency in the core subjects that they teach. (According to NCLB, these core subjects are English, reading or language arts, math, science, history, civics and government, geography, economics, the arts, and foreign language.)

Teacher preparation programs in colleges of education in the United States continue to vary from institution to institution despite the NCLB. Prior to NCLB, standards to improve the practice of teaching were created by various groups that include the National Board for Professional Teaching Standards (NBPTS), formed in 1987; the Interstate New Teachers Assessment and Support Consortium, known as INTASC, also formed in 1987; and the National Council for Accreditation of Teacher Education (NCATE) and the Teacher Education Accreditation Council (TEAC), which oversee teacher education programs throughout the United States.

One way in which certification standards are being raised for the beginning teacher is through initial licensure based on INTASC's 10 principles, which are focused on ensuring that teacher certification is a guarantee of a beginning teacher's knowledge and skill. These 10 principles are descriptions of a beginning teacher's competency in the areas of subject matter, learning styles, instructional methods, child development, learning environments, communication, planning, assessment, reflective practices, and community partnerships.

For experienced teachers, the obtaining of national board certification is a credential that affirms the expertise of accomplished teachers. National certification in teaching is awarded to expert teachers by the NBPTS and is designed to complement previously earned state teacher certification. The NBPTS, an independent organization with no government affiliations, lists five core propositions as the foundation of its standards: (1) commitment to students and learning, (2) knowledge of content and pedagogy, (3) management and monitoring of student learning, (4) reflection on the profession of teaching, and (5) participation in a learning community. The NBPTS offers 24 possible certificates in 15 subject areas and 7 age categories with two generalist certificates.

The rigorous requirements of the national board certification voluntary process were developed to promote and recognize excellence in teaching. In addition to registration fees, which are often borne by the local school districts of the applicants, candidates must provide an extensive portfolio (including videos of actual teaching) that documents accomplishments, excellence, and expertise. Candidates must also pass a series of essay-type tests as required by NBPTS. As of December 2006, there were approximately 50,000 teachers nationwide who were certified by the NBPTS.

CHARTER SCHOOLS

Charter schools are public schools that are allowed greater autonomy than traditional public schools in exchange for increased accountability for meeting specific educational goals. Individual states' charter school laws vary tremendously, but charter schools generally operate as deregulated public schools, using public funds to support programs founded by parents, educators, community groups, or private organizations. State laws identify public entities like local school boards, universities, or state boards of education to evaluate proposals and grant a limited number of charters or contracts for establishing schools.

Charter schools are often launched to focus on a unique educational vision (e.g., Montessori), gain autonomy from embattled local districts, or serve a special population (e.g., children at risk of expulsion). The degree of autonomy enjoyed by charter schools varies but usually involves school-level decision-making authority over curriculum design, schedules, budget outlays, and hiring. The same entities that authorize charter schools are responsible for monitoring and ultimately closing charter schools that fail to demonstrate evidence of success by the end of a time period established by the charter, usually 3 to 5 years. Before discussing the potential and challenges of charter schools, it is useful to understand the origins of the charter school movement, the relationship of charter schools to the broader issue of school choice, and the popularity of charter schools.

The Charter School Movement

The charter school movement is young but has gained popularity as a mechanism for encouraging innovation and providing public school choice. The paragraphs that follow trace the growth of charter schools from their humble beginnings in Minnesota to their place today in mainstream public education.

Origins of the Charter School Concept

The earliest mention of the term *charter school* can be traced to the 1970s when a New England educator suggested that new educational approaches could be explored through contracts given to small groups of teachers. The idea was publicized in the late 1980s when a former president of the American Federation of Teachers suggested that local school boards could "charter" a school with union and teacher approval. Philadelphia dubbed their schools-within-schools initiative in the late 1980s "charter schools." In 1991, Minnesota passed the first charter school law developing a program to provide opportunity, choice, and responsibility for results. The following year, California followed suit.

Charter Schools and School Choice

The charter school concept has joined the ranks of school choice designs, including magnet schools, open enrollment, vouchers, and tax credits. Over the past 10 years, states and school districts have expanded opportunities for parents to use public funds to choose the schools their children attend in attempts to improve the quality of education available to students, particularly in urban areas.

Supporters contend that school choice can improve the public education available to all children based on two crucial factors. First, public school choice levels the playing field for less affluent families. Parents with financial resources can choose their children's schools through investing in private education or by virtue of the neighborhoods in which they choose to

live. School choice provides educational alternatives for families without these resources. Second, school choice proponents argue that competition among public schools serves the diverse needs of students more efficiently than a system requiring students to attend neighborhood schools. Market forces would, in theory, force all schools to improve in order to survive. When parents have the opportunity to choose strong schools, less effective schools lose students and ultimately close. These arguments have led to increasing popularity of school choice programs in general and charter schools in particular.

Criticism of School Choice

In spite of support for school choice from across the political spectrum, the concept is not without its detractors. Charter schools are a target of criticism because they are a prominent and growing example of the popularity of school choice programs. Detractors' concerns revolve around possible cultural isolation and racial resegregation in schools of choice as well as potential detrimental effects for students left behind in neighborhood schools.

A more balanced view suggests that school choice is not inherently good or bad, but its effects depend on policy decisions and their implementation. Big city school districts find themselves in a quandary for a way to gain consensus on a strategy for school reform. Charter schools are appealing because they appear to be a way out, but opponents' concerns should alert policymakers to potential drawbacks. Problems can be minimized through well-reasoned policy decisions in addressing the monumental challenges of improving the public education.

Popularity of Charter Schools

In spite of the controversy surrounding school choice, the popularity of charter schools has grown tremendously in a short period of time. Charter schools are a recent phenomenon, with the first school established just 15 years ago and the average age for all charter schools standing at only 5 years. Even so, they have quickly become a small but growing part of the mainstream educational system. In 2005, charter school laws were on the books in 40 states and the District of Columbia. Although laws varied dramatically from state to state, more than 3,000 charter schools were operating in the 2004–2005 school year.

Estimates of the number of children attending charter schools range from 750,000 to 1 million, or roughly 2% of all public school students. Nationally, the number of charter schools grew faster in 2004–2005 than in any of previous four years, adding almost 500 new schools. The states that opened the largest numbers of new charter schools were California, Colorado, Florida, Michigan, Minnesota, Ohio, and Wisconsin.

Great disparity exists among states in terms of the number of charter schools. With more than 500 charter schools in operation, California and Arizona top all other states in terms of sheer numbers. In fact, six states (Arizona, California, Florida, Michigan, Ohio, and Texas) account for almost two thirds of charter schools and charter school students. On the other hand, Washington, D.C. charter schools have the largest share of public school students of all states at almost one in four. In fact, although the total number of schools pales in comparison, a much higher portion of public school students in Washington, D.C., Delaware, and Colorado attend charter schools than in Texas or California.

Potential and Challenges of Charter Schools

The growth in charter schools comes from optimism that they can address many of the difficulties facing public education. Supporters anticipate that the autonomy afforded charter schools will foster innovation and ultimately lead to the development of better schools. Furthermore, they argue that increasing the number of schools from which parents can choose will lead to more balanced ethnic diversity across schools and improved educational outcomes. The hope and reality of each of these expected benefits of charter schools are explored in more detail in the paragraphs that follow.

Innovation in Charter Schools

Charter school supporters foresee innovation emerging from charter schools because of the autonomy they enjoy across many areas, including personnel, curricula, and schedules. Employees of charter schools do not typically belong to local teachers' unions and are considered at-will employees who can be fired for poor performance or compensated for superior service. In addition, alternative certifications may be an option for charter school teachers, bringing skilled individuals into

schools who may not otherwise consider teaching. Such an environment would be conducive to novel teaching methods, but the National Education Association argues that less stringent teaching credentials will lead to inferior educational quality. In addition, the association contends that charter school employees should have the same collective bargaining rights as any public school employees.

Flexibility to differ from district-mandated curricula contributes to the potential for innovation in charter schools. Many charter schools adopt specific curricular programs ranging from character education to technology themes. Freedom for charter schools to set their own schedules allows them to offer variations such as year-round schooling, extended days, or block schedules. In addition, many offer grade configurations unavailable in neighborhood schools, such as kindergarten through eighth or even twelfth grade. Charter schools are also more likely to use structures allowing student groups to remain with the same teacher for more than one year (called looping). Such unique programs are unlikely to be available in traditional public schools, giving parents real choice in finding the best schools to fit their children's needs.

Diversity in Charter Schools

As envisioned by school choice advocates, charter schools have the potential to create better school options for low-income and minority children in urban areas. Nationally, charter schools serve a higher proportion of minority and low-income students relative to traditional public schools primarily because more charter schools exist in urban areas. About a third of states require charter schools' ethnic composition to mirror that of their districts, and some require random processes like lotteries for admission when demand exceeds available seats. However, achieving racial targets is not a fundamental aspect of charter school operation as it is for magnet schools. In fact, some charter schools incorporate cultural heritage themes (e.g., African- or Native Hawaiian-based curricula), which results in less diversity within a given school.

Charter schools' success in providing viable alternatives for all parents is hindered because the families who would most benefit from the availability of public school alternatives often lack resources to take advantage of them. First, transportation or before- and after-school care can seem to be matters of convenience, but they are vitally important to some families' livelihoods.

Because few states provide transportation to charter schools, they are out of reach of those without a means of providing it themselves. As evidence of this, studies have shown that lower-income parents rate so-called convenience factors as more important, whereas higher-income parents placed more weight on a school sharing their philosophy.

Second, parents need information to understand and evaluate school options, and limited information access may create hurdles for the most disadvantaged students' families. Schools with a first-come first-served enrollment policy likely hinder families with less timely or sophisticated means of gathering information. As evidence of this dilemma, studies indicate that parents who participate in school choice have higher education levels than those who have a choice but fail to pursue it.

Finally, the reality of parental decision making can hamper efforts to increase racial diversity in schools. Studies suggest that parents report being most concerned about educational quality, but their behavior demonstrates a preference for schools that are close to home where their children are in the racial majority and the school body mirrors their own family's socioeconomic status. In fact, household race has been shown to be the strongest predictor of the racial composition of the charter school selected.

One largely unexplored aspect of diversity in charter schools is the degree to which they serve students with special needs. On average, charter schools enroll a somewhat smaller proportion of special education students nationally than traditional public schools. Once again, the data differ from state to state, with New Mexico and Ohio serving a larger proportion of students with special needs. This disparity stems from differences in goals established for charter schools in individual states. For example, some states emphasize charter schools serving students at risk of failure, which would tend to overrepresent students with special needs in charter schools. However, the concern exists that students who need additional services may be steered away from charter schools in a manner that would be discriminatory.

Educational Outcomes in Charter Schools

Charter school advocates claim that educational outcomes will improve as a result of creating alternatives to traditional public schools. However, the contradictory research findings on the academic success of

charter schools are staggering. Most studies on both sides of the debate suffer from serious methodological or data limitations. As with all educational research, identifying a reasonable comparison group is a major challenge. Two methods of creating comparison groups are reasonable but come with their own limitations. First, charter school attendees can be compared to students at comparable nearby schools. The problem is in controlling for the fundamental differences between parents who take advantage of choice when it is available and those who do not. Second, charter school attendees who won seats in a lottery can be compared to students who were not chosen. This design controls for the self-selection problem identified previously but limits analysis to schools with long waiting lists, which in itself introduces bias.

The tremendous variety of charter school laws across the country creates another fundamental challenge for researchers. Simply lumping together all charter schools regardless of their program or population and comparing them to the average public school is fraught with problems. Some charter schools target poor and disadvantaged students or students at risk of failure. Others seek to provide enrichment opportunities for students who excel. Some charter schools are funded comparably to nearby public schools, but most receive much less money. Finally, some charter schools operate in supportive local environments, whereas others must expend resources to defend their schools from antagonistic school districts or teachers' unions. Clearly, considering all charter schools as members of a homogeneous population is an oversimplification at best.

In spite of the difficulties, high-profile studies have been conducted attempting to answer questions about the educational success of charter schools. In 2004, the American Federation of Teachers and the National Assessment of Educational Progress reported that charter school students had lower achievement than public school students and that charter schools had a larger achievement gap between those who were and were not eligible for free and reduced lunch, a common proxy for family socioeconomic status. A subsequent Harvard University study encompassing 99% of charter school enrollments compared charter schools with schools students would most likely otherwise attend. This study found that charter school students were more likely than students in matched schools to be proficient in reading and math on state exams. Similarly, two national organizations with opposing views on charter schools reviewed existing charter school research and released contradictory findings in the spring of 2005.

As a result of the confusion in reconciling research on charter schools, the National Charter School Research Project is attempting to provide a balanced perspective and has committed to reviewing all available studies on the subject of charter school attendance and academic achievement. In all fairness, the state of research on charter schools is not surprising given the youth of the charter movement and the great disparity in programs across states. Definitive findings will come from an established body of work finding consistent results across settings and research designs. Such a body of knowledge is necessary to create a firm foundation for policy decisions, but it accumulates slowly over time.

Charter School Accountability

In exchange for increased autonomy, the charter school bargain requires increased accountability for results. However, differences in states' charter school laws lead to dramatic disparity across states in their respective charter schools' goals, standards of success, and consequences for failure. Generally speaking, charter schools can be closed if demand is low, if they fail to uphold their financial and operational commitments, or if they fail to satisfy the terms of their charter agreements. Even so, relatively few charter schools have been closed. During the 2004–2005 school year, only 65 charter schools, or 2% of the total, closed their doors in 17 states and the District of Columbia. As with all aspects of charter schools, the volume of closures varied from state to state, ranging from no closures in 15 states to 21 schools closed in California.

Both sides of the charter school debate attempt to use charter school closings to bolster their arguments. Supporters maintain that the small number of closures is a sign of charter schools' success, whereas opponents argue that few closures mean too many schools remain in operation regardless of performance. Whenever a charter school does close, supporters claim it is simply evidence that accountability works and consequences are real. Detractors contend that a closure is evidence of inherent flaws in the charter school concept. Ideology aside, closing a charter school is often difficult because even poorly performing charter schools can be tremendously popular with parents, especially when other available public schools are even worse.

Unfortunately, the autonomy enjoyed by charter schools allows room for misbehavior by inept and unscrupulous school leaders. Such was the case in the summer of 2004 when a for-profit, multisite Education Management Organization (EMO) in California faced closure of more than 60 campuses serving almost 10,000 students. In spite of overwhelming numbers, the California Charter School Association helped find new schools with little disruption for students. Students were distributed across California in small schools, and most were accommodated in one of the state's other charter schools. Although it is easy to place blame on the school management company, the local district contributed to the problem by failing to exercise oversight and ignoring ongoing poor performance.

To avoid public debacles like this, some states and the National Association of Charter School Authorizers are pushing pro-accountability standards for authorizing and monitoring charter schools. With tighter reins, intervention is possible before a problem grows to such a scale. For example, steps can be taken to strengthen a troubled school or make management changes at the first signs of problems. As counterintuitive as it may sound, some advocates suggest that the availability of more charter schools would reduce the impact of school closings because competition would draw students away from weak schools before a charter is revoked.

The Future of Charter Schools

In order for charter schools to realize their promise, advocates admit that many obstacles must be overcome. Charter schools have the potential to significantly increase the number of schools from which parents can choose, but a sufficient number of schools must be available to have an impact on the market. Achieving the scale necessary to successfully serve more than a small fraction of public school students requires changes to state laws, equitable funding, and plans for expanding proven models.

Charter School Growth

Even with their popularity to date, the future growth of charter schools is in question because of limits established in many states. Lawmakers often place limits on the growth of charter schools in their states as a means of political compromise. Twenty-seven states have restrictions on the growth of charter schools, most placing a ceiling on the number of new charter schools

that may open statewide, in cities, or under specific authorizing agencies. Other states limit growth by setting a maximum number of students enrolled in charter schools or limiting district spending on charter schools. Under constraints in place in 2005, only 725 more schools would be allowed across the country, and almost half of these (340) would be in California. Other leaders in the number of charter schools taken together, Michigan, Ohio, and Texas, are permitted just 29 additional schools under existing legislation.

Although legislative change will be required for the growth of charter schools to continue, pressure to lift existing limits may come from converting failing public schools to charter status. Specifically, provisions of the sweeping No Child Left Behind (NCLB) legislation allow low-performing schools to convert to charter status as part of their restructuring plans. If a school fails to achieve adequate yearly progress for 5 years in a row, it must be restructured in one of five ways: reopen as a charter school, replace the staff, contract with a private company for operations, allow state takeover, or implement some other major governance change. In the 2004–2005 school year, about 400 schools in 14 states have reached the 5-year mark, with another 750 schools in 31 states only 1 year away from reaching the limit. Even before NCLB would force restructuring, several districts, including Denver, New Orleans, San Diego, and Chicago, are beginning to convert failing schools to charter status.

The primary benefit of converting failing schools to charter status is the opportunity for new staff and a new program with the flexibility to address unique student needs. Not surprisingly, drawbacks exist to converting failing schools to charter status. In an attempt to find an easy solution to dealing with school failure, school districts could simply make the switch to charter status without making any substantive changes in the school operations. This strategy could buy time but would be unlikely to improve the school quality to benefit students. An honest commitment to restructuring a failing school as a charter school requires substantial district resources, from recruiting potential managers, administering the charter application and negotiation process, and involving the community to monitoring start-up and ongoing operations.

Funding Charter Schools

Funding inequities pose as serious a challenge to the future growth of charter schools as state caps.

Attempting to compare charter school funding to other public schools is fraught with many of the same issues as evaluating outcomes. For example, each state structures funding differently depending on student populations served and funding sources available. Furthermore, charter schools often pay for services not included in traditional public school budgets (transportation, oversight, etc.), and some districts provide services at no cost to district-run schools but not to charter schools (assessment, insurance, and services for students with special needs, etc.). Complicating matters, school district financial recordkeeping is not very sophisticated, so fiscal data are not readily available and accessible to researchers.

In spite of these issues, research that accounts for these methodological challenges makes it clear that the greatest funding inequity for charter schools comes from lack of access to incremental local budget dollars above state funds and from restrictions on funding for facilities. A 2005 study released by the Thomas B. Fordham Institute found charter schools underfunded relative to other district-run schools in the vast majority of communities examined, with the discrepancies being larger in most big urban school districts. The gap in 2002–2003 ranged from equity in Minnesota and New Mexico to gaps of more than 25% in Missouri, Wisconsin, Georgia, Ohio, California, and South Carolina. On a per-pupil basis, the average discrepancy is $1,801, which translates to almost a half-million-dollar shortfall every year for an average-sized charter school.

Achieving Scale in Charter Schools

In order for charter schools to become a serious force for improving education nationally, a sufficient number must exist to serve as viable competition for traditional public schools and to provide options for more than a fraction of students. Some charter school advocates laud the grassroots nature of many charter schools started by groups of committed teachers or parents. However, this approach alone is unlikely to produce the scale necessary to affect the quality of schooling nationwide.

One way of expanding the availability of proven charter school models is through EMOs. Most EMOs are for-profit companies like Edison Schools and Nobel Learning Communities, but most for-profit EMOs have yet to show a profit. Nonprofit EMOs like Aspire Public Schools exist as well. At present, only 10% of charter schools are operated by EMOs, and they tend to be larger than the average charter school. As with all aspects of charter schools, however, striking differences exist across states, with some restricting such organizations from operating in their territory by law. Alaska and Minnesota have no EMOs operating charter schools, whereas three quarters of Michigan charters are operated by EMOs, the largest proportion of any state. EMOs offer many resources for charter schools, including a leadership training ground, expertise and management systems, economies of scale, incentive and capacity to sustain schools over a period of time, and investments for research and development and possibly facilities.

Other designs attempt to merge the best of both worlds by leveraging the resources and support of experienced charter school organizers while maintaining the spirit of the independent charter school. Some examples include KIPP Academies in Houston and the Bronx, Minnesota New Country School/EdVisions, and High Tech High. KIPP Academies hope to help open 200 schools across the country by 2010. They are not part of an EMO because each school operates as an independent entity following the basic principles espoused by KIPP in its training and ongoing support programs. Minnesota New Country School/EdVisions is a high school design run by teacher cooperatives with learning through a personalized, project-based curriculum. The organization hopes to start 15 new secondary schools over 5 years with help from The Bill and Melinda Gates Foundation. High Tech High is a proven charter school model incorporating a rigorous personalized math, science, and technology curriculum with ties to the adult world. In 2006, The Bill and Melinda Gates Foundation awarded High Tech High $7.5 million over 3 years for new middle and high schools in California.

Replicating successful school models is likely to be the future direction for achieving charter school growth. Many envision fewer for-profit EMOs as well as a smaller proportion of individual start-up schools. Significant high-profile support exists for expanding the reach of charter schools. Organizations like The Bill and Melinda Gates Foundation are focusing on replication grants for expanding "successful" charter schools. The foundation's funding of charter schools is part of its ongoing commitment to fostering innovative educational programs and encouraging public engagement in improving education. The bulk (80%) of the support of the Walton Family Foundation,

which is devoted to education funding, is directed to charter schools. Their efforts range from direct support of new charter schools to funds for charter school management companies, technical assistance organizations, advocacy groups, and research. The founder of the Gap clothing store, Donald Fisher, is also an active contributor to charter schools. These influential philanthropists seem to share advocates' optimism in the potential for charter schools to improve education.

Future of Charter Schools

The charter school movement has gained popularity because of its potential to expand public school choice and improve public education. Predicted charter school benefits include innovation, higher-quality education, diversity, and accountability. The future of charter schools depends on policies that mitigate concerns about the possible downside of school choice. At the same time, further growth of charter schools requires individual states authorizing additional schools, equitable funding for charter schools relative to other district schools, and plans for achieving widespread growth of proven models. Although it is too early to declare charter schools a success or failure and intense study is just now beginning, charter schools' presence in mainstream public education and their high-profile support suggest that they are here to stay.

CHEATING

Cheating involves an act of deception, fraud, or betrayal that often unfairly advantages the cheater over others. It can take many forms. The variety of behaviors it entails, and the wide range of contexts in which it occurs, is as diverse as the human species itself. From infidelity in the bedroom to malfeasance in the boardroom, people betray, trick, deceive, and defraud each other (and sometimes themselves) in a number of creative (as well as mundane) ways and places. This entry focuses on academic cheating and will describe several important facets or subcomponents related to the psychology of cheating.

Definitions and Typologies of Academic Cheating

A cursory review of the literature suggests that there is no universally embraced definition of academic cheating. For example, some researchers have defined cheating indirectly and vaguely, such as "a violation of an institution's policy on honesty," whereas others seem to have left the meaning of cheating up to students' interpretation by asking them directly how often they "cheat" on their work or use "cheat sheets" when they take tests. More typically, researchers have avoided such ambiguity or subjectivity, respectively, by asking students how often they have engaged in a specific set of behaviors, such as "copying from a neighbor during an examination" or "copying material without acknowledging the source." This latter approach is sometimes combined with a corresponding set of questions that asks students if they consider the behavior "cheating" or to rate how "serious" they think it is. Not surprisingly, the more likely students are to define a behavior as "cheating," the less likely they are to report engaging in that behavior.

In addition to the wide variation in how researchers have operationally defined cheating, several investigators

have created various typologies of cheating. Gary Pavela, for example, described four general types of academic dishonesty: (1) the use of unauthorized materials on any academic activity (e.g., using "cheat sheets" during an exam); (2) fabrication of information, references, or results (e.g., falsifying lab results); (3) plagiarism (e.g., copying verbatim another's work without proper attribution); and (4) helping others engage in academic dishonesty (e.g., allowing another to copy your homework). Stephen Newstead and his colleagues conducted an exploratory factor analysis on 21 academic behaviors and derived the following five factors: (1) plagiarism (which included a fabrication item); (2) collaborative cheating; (3) exams, collusion; (4) lying (e.g., lying about a medical condition to get an extension); and (5) exams, noncollaborative. More recently, some researchers have made a distinction between traditional or conventional cheating and digital or Internet-based cheating.

Academic cheating or dishonesty (the terms are often used interchangeably) has been defined in numerous ways, and various typologies have been constructed in an effort to map its vast terrain. Taken together, academic cheating can be defined broadly as the use of unauthorized or unacceptable means in any academic work. The means or actions include, but are not limited to, lying, using crib notes during exams, copying other people's work without permission, altering or forging documents, purchasing papers, plagiarism, unpermitted collaboration, altering research results, and providing false excuses to miss assignments or make up exams.

The Epidemic of Academic Dishonesty

Academic dishonesty is a pervasive problem in secondary and postsecondary institutions. By most accounts in the literature, the majority of students seem to be doing it and doing it in more than one way. For example, in its 2006 Report Card on the Ethics of American Youth, the Josephson Institute of Ethics found that 60% of secondary students reported cheating during a test at school within the past year (35% did so two or more times), and 33% reported plagiarizing material from the Internet (18% did so two or more times). Donald McCabe has found similar numbers in his national surveys of college undergraduates: 70% admit to engaging in some form of cheating, nearly 25% admit to "serious" test cheating,

and 40% to Internet plagiarism (77% of students don't believe such plagiarism is very serious). The problem is also prevalent at graduate schools, especially business schools, where 56% admitted to some form of academic dishonesty (i.e., copying other students' work, plagiarizing, or using prohibited materials on an exam) within the past year.

The high frequency of academic cheating is not a new problem—it's been labeled an epidemic numerous times since at least the 1980s—but there is evidence suggesting that it has grown over time. In "Schooling Without Learning: Thirty Years of Cheating in High School," Fred Schab documented the upward trend of academic dishonesty among high school students over the course of three decades. For example, in 1969, only 33.8% of students indicated that they had "used a cheat sheet on a test"; 67.8% admitted doing so in 1989. Letting other students "copy your work" moved from 58.3% in 1969 to 97.5% in 1989. Similar trends have been reported among college students. More recently, some have claimed that the Internet has *caused* a spike in plagiarism. Although such a concern is warranted (cutting and pasting is, after all, much quicker and easier than retyping word for word), research data suggest otherwise. First, plagiarism rates have not grown significantly, if at all, since the rise of the Internet in the early 1990s, and second, most students who report using the Internet to plagiarize also report using conventional means to do so. In short, the Internet does not appear to be creating a new generation of plagiarists and is probably best described as a conduit to, not a cause of, such cheating.

The Demography of the Dishonest

The title of this section, "The Demography of the Dishonest," is intentionally misleading. It reflects the common assumption that only certain "bad" people cheat, and the rest are "good" people who would never do so. The preceding section on the prevalence of cheating illustrates the faultiness of this assumption. The stark reality is that most students cheat at some point each and every year from middle school to graduate school. Therefore, the question isn't "Who does it?" (every type of student cheats—male, female; younger, older; Black, White; etc.), but rather "Who does it more often?" With this in mind, there are some demographic characteristics that have been associated with cheating.

In his meta-analysis of more than 100 published studies of undergraduate cheating (for the practical reason of access as well as the ethical requirement of obtaining parental consent, there are relatively few studies of cheating among middle and high school students; not enough, that is, to conduct meta-analyses and ascertain meaningful patterns), Bernard Whitley found age and marital status to be the most significant demographic predictors of cheating; specifically, younger and unmarried students were more likely to cheat than older and married students. Sex, parental financial support, on-campus residency, and number of hours of employment produced small effect sizes; specifically, cheating was more prevalent among students who were male, received more financial support from their parents, lived on campus, and were employed for fewer hours per week. Some researchers have used the terms *immaturity* and *lack of commitment* to describe or explain cheating among students with a combination of the demographic characteristics (e.g., young, unmarried, funded by parents, and unemployed).

Although academic ability or achievement, as measured by grade point average (GPA), is not necessarily a demographic variable, it has been included in numerous studies of cheating. As with most demographic variables, GPA seems to have only a small relationship to cheating in college; undergraduates with lower GPAs report higher levels of cheating. Again, data at the secondary level are scant, but according to the 29th Annual Survey of Who's Who Among American High School Students, 80% of the United States' best and brightest students reported cheating to get to the top of their class. This study and others suggest that the percentage of high-achieving students who cheat is comparable to that of lower-achieving students. It may be, however, that cheating among high-achieving students may be strategic and selective, and therefore "less" in an absolute sense.

In sum, there is no demographic profile for "cheaters"; most students cheat at some point. And although age, sex, marital status, and so on may be correlated with cheating, these demographic variables are almost never strong predictors of cheating. This is especially true when the conceptual model and statistical analyses of the study include psychological, social, and contextual factors. In other words, cheating is a complex problem. Any attempt to understand it more fully must go beyond demography and examine the more potent psychological processes that lead to cheating.

Morality, Motivation, and Misconduct

One of the most insidious aspects of academic cheating is that most students who report doing it also report believing that it is wrong to do. Why, then, do they do it? This question has been approached by numerous scholars in a wide variety of ways. The most direct way, of course, is to simply ask students why they cheat. Studies that have done so have yielded a fairly consistent pattern of results: pressure for grades, perceptions of poor teaching, time constraints, and lack of interest are typically among the primary reasons students cite when asked why they cheat in school. Although this approach may be the most straightforward and efficient, it is also atheoretical and superficial. For deeper insights into the question of why students cheat, even when they believe it is wrong, we need to turn to theory-driven studies that have employed more sophisticated research methods.

Some of the earliest and most prominent research on academic cheating focused on moral character to explain why some students did it and others did not. Contrary to expectations, Hugh Hartshorne and Mark May in their classic *Studies in Deceit* did not find evidence that honesty was a fixed, individual trait that reliably differentiated cheaters from noncheaters. Instead, situational factors, such as risk of detection and group approval, were the most influential factors in determining cheating behavior. Similarly, later studies that investigated the relations between moral development and academic cheating found that students with high reasoning ability cheated just as much as low-level reasoners when the threat of detection was low and the potential reward high. This is consistent with broader findings that moral judgment and moral action are not highly correlated, and the other components of moral functioning need to be accounted for.

Lawrence Kohlberg and his colleagues, for example, theorized that the relationship between moral development and moral action was mediated by two distinct but related types of moral judgment: deontic and responsibility. They described deontic judgment as a first-order judgment concerning the rightness or wrongness of a given action (deduced from a moral stage or principle), and responsibility judgment as a second-order affirmation of the will to act in terms of that judgment. Presumably, students who report cheating, despite having rendered a deontic judgment

that it was wrong to do so, did not make a judgment of responsibility; that is, they did not feel a sense of personal accountability to "follow through" and "perform the right action." Very few studies on academic cheating have directly tested this hypothesis, and those that have used the construct of "moral obligation" to do so. Conceptually, moral obligation and responsibility judgment are very similar, and, as expected, students who reported feeling a stronger moral obligation to refrain from cheating were less likely to report doing so.

Other psychologists as well as sociologists have also been interested in explaining the gap between moral judgment and moral action, and they have offered what might be considered the antithesis of Kohlberg's responsibility judgment or moral obligation: moral disengagement or neutralization of personal responsibility. Minimizing consequences (e.g., it's "no big deal"); euphemistic labeling (or nonlabeling, not acknowledging cheating as "cheating"); and displacing responsibility (blaming others) are three of the many disengagement mechanisms or neutralization techniques that individuals use to avoid or reduce self-recrimination when they have behaved criminally or immorally. Empirical research has demonstrated strong positive associations between cheating and moral neutralization. Displacement of responsibility seems to be the most prevalent strategy neutralization technique used by undergraduates: 61% of students who reported cheating rationalized their cheating by blaming others and/or some aspect of the situational context. Similarly, a study of high school students revealed that they were most likely to blame their cheating on teachers, and that this displacement of responsibility to the teacher was most pronounced among high-achieving and college-bound students.

Interview studies suggest that many students are aware of the incongruity between their beliefs about cheating ("It's wrong") and their behavior ("I do it"). They acknowledge the incongruity but are quick to dismiss it for the pay out of higher grades. In other words, students' academic motivation (pursuit of high grades) can trump their moral judgments. One of the most well-established approaches to understanding students' academic motivation is achievement goal theory, which posits the existence of two types of achievement goals: (1) to develop ability, often called a mastery or learning goal; and (2) to demonstrate ability (to avoid the demonstration of a lack of ability), often called a performance goal or ego goal.

Mastery goals orient individuals toward developing their knowledge, learning new skills, and using self-referenced evaluation criteria. Performance goals focus individuals on appearing smart relative to others, displaying skills, avoiding the appearance of inability, and using norm-referenced evaluation criteria. In educational settings, both types are posited to exist at three levels—school, classroom, and personal. Furthermore, students' goal orientations are thought to be situational, not dispositional—the extent to which a student is mastery and performance oriented is determined (at least in part) by the classroom goal structures, which are themselves partially determined by the school goal structures.

Over the past 10 years, numerous studies have used goal theory to further researchers' understanding of academic cheating. Studies at this intersection of goal theory and cheating have evolved over the past decade and fall into four basic types: (1) interindividual differences, (2) intraindividual differences, (3) longitudinal, and (4) experimental. In general, these studies have shown that mastery goals are negatively associated with cheating; students are less likely to cheat when they are focused on developing their competence and/or they perceive that classrooms or schools are focused on the development of their competence (these "messages" are communicated verbally through an emphasis on learning and effort as well as nonverbally through instructional and assessment practices). On the other hand, performance goals are generally positively associated with cheating; students are more likely to cheat when they, their classrooms, or their school are focused on demonstrating competence (through, for example, the attainment of high test scores and grades).

In sum, both morality and motivation matter in the perpetration of academic misconduct. In an interesting study that combined these typically distinct approaches to understanding cheating, Tamera Murdock and her colleagues used hypothetical vignettes to isolate the effects of classroom goal structures and teacher pedagogy on students' beliefs about the acceptability and likelihood of cheating. Consistent with previous research, they found that students believed cheating to be more justifiable (as well as more likely) when the classroom in their hypothetical vignettes was portrayed as focused on grades and the teacher as a poor instructor. They also assessed students' belief about the morality of cheating (i.e., an absolute, as opposed to context-dependent, belief

about rightness or wrongness of cheating). Not surprisingly, students' beliefs about the morality of cheating were less influenced by contextual factors and less strongly related to the perceived likelihood of cheating; students believe cheating to be morally wrong (regardless of circumstances), but this judgment doesn't much affect their likelihood of cheating.

The Power of the Situation

Individual behavior does not occur in a vacuum; social and situational circumstances exert a powerful influence on personal choices and actions. As discussed in the previous section, students' perceptions of classroom and school goal structure affect not only their cheating behavior but also their judgments about the acceptability of cheating. Also, as discussed above, students' perceptions of teachers' pedagogical competence affect cheating behavior and so, too, do their perceptions of teacher fairness and caring: Students are more likely to cheat when they perceive their teachers to be incompetent, unfair, or uncaring.

In addition to these subjective perceptions of teacher qualities, the subject matter also matters. Students report cheating most often in math and science courses and least often in social science and humanities courses. Susan Stodolsky's comparative analysis of math and social studies provides some insights into why students may cheat more often in math and science classrooms. Namely, the activity structures ("drill and kill") and assessment practices (objective, multiple-choice tests) often employed in teaching these domains provide more frequent and accessible opportunities to cheat. However, more research is needed. It may be, for example, that only certain types of cheating (e.g., homework and test-related behaviors) occur more frequently in math and science courses and that other types of cheating (e.g., plagiarism) are more likely to occur in social science and humanities courses.

Although all of the foregoing situational factors (real or perceived) have been significantly associated with cheating, peer norms (attitudinal and behavioral) tend to be the most powerful predictors of cheating behavior. For example, Donald McCabe and Linda Trevino's large-scale, multi-institutional study of individual and contextual factors associated with cheating in college found disapproval of cheating, peer cheating behavior, and fraternity/sorority membership to be the three most influential factors associated with cheating. Specifically, students who perceived that

their peers disapproved of academic dishonesty were less likely to cheat, whereas those who perceived higher levels of cheating among their peers and those who belonged to a fraternity or sorority were more likely to report cheating. Moreover, peers are very reluctant to report the cheating of others, even at institutions with so-called rat clauses that require students to do so. Put another way, cheating has become normative behavior among secondary and postsecondary students—it is widely seen and acceptable. Reporting others for cheating, in contrast, would be socially deviant behavior—rarely seen and greatly shunned. Finally, students who cheat rarely get caught. If caught, they are seldom punished severely, if at all.

Strategies for Promoting Academic Integrity

There are many ways that faculty, administrators, and institutions as a whole have attempted to address the problem of academic cheating in their classrooms or on their campuses. Many focus on the prevention and detection of cheating, but others have taken a somewhat different approach: the promotion of academic integrity. Although the promotion of academic integrity could be construed as a method of prevention, it is much more than that. Efforts to foster academic integrity, which are done most effectively at institutions with honor codes or committees, provide students with multiple opportunities and role models for learning the importance of understanding and concern for core academic values, such as honesty, trust, fairness, respect, and responsibility. Detecting and disciplining students who cheat must be part of any holistic approach, but it should not be the primary strategy to address the problem. Educational institutions at all levels should help students understand the meaning and importance of scholarship, intellectual property, and integrity. They should also help students develop the will and skill to participate in academic life in a fair, honest, and responsible manner.

Research indicates that students at institutions with honor codes are half as likely to report cheating on tests and one third as likely to report engaging in plagiarism. These reductions are far greater than any other approach known at this time. Unfortunately, relatively few institutions (particularly at the secondary level, where the problem of cheating begins to flourish and, therefore, the need is arguably the greatest) have invested the time and resources to transform the

culture of integrity on their campuses. This, despite the fact that there are now several organizations, such as The Center for Academic Integrity, that offer a wide range of materials and support for doing so. This being the case, the following strategies are offered as ways to mitigate the probability of cheating.

Reducing In-Class Test Cheating

The following are simple strategies that faculty can implement and should use, especially in larger lecture-based courses:

- Space Seating and Monitor: Where possible, students should be spread out (leaving a space between them), and faculty should move about the room throughout the examination.
- Create Multiple Forms: Whether or not spacing is possible, faculty should create multiple forms of their exams, randomizing both the order of questions and the answers.
- Ban Digital Technologies: Given the raise in digital forms of cheating, faculty should ban the use of cell phones, PDAs, calculators, laptops, and so on during exams.

Reducing Plagiarism

- Make Writing Assignments Clear and Manageable: Provide students with a list of specific topics or require components.
- Require Process Steps: Help students avoid last-minute, late-night plagiarism by requiring a series of process steps—topic identification, outline, first draft, peer exchange—that precede the final draft.
- Meet With Students to Discuss Their Research Papers: Where possible, meet with students individually to discuss their papers.

Detecting Plagiarism

- See the Signs: Make sure the paper addresses the specified topic or requirements, and take notice of changes in the voice or style of the writing, mixed citation styles or formatting, anomalies in diction, and so on.
- Know the Enemy: Faculty members should familiarize themselves with the online sources of plagiarism, such as Cheathouse, School Sucks, Screw School, and The Paper Store.
- Use a Plagiarism Detector: When plagiarism is suspected, faculty should use a text-matching program such as Turnitin.com to ascertain whether plagiarism has, in fact, occurred.

General Pedagogical Advice

Faculty can help students adopt mastery goals and develop academic efficacy with the following techniques:

- Engage: Create learning experiences that tap students' interest.
- Challenge: Provide optimal challenge and scaffold learning experiences.
- Empower: Give students a sense of control over the learning process and the products they create.

By taking the following actions, the faculty can help create an academic climate that emphasizes mastery over performance:

- Diversify: Design a multidimensional learning environment where expertise is distributed.
- Recognize: Emphasize and acknowledge students' efforts to learn and understand, not test scores.
- Privatize: Provide private individual evaluation of progress and avoid practices that invite social comparisons of performance differences.

In addition, the faculty can create a just and caring learning community by implementing the following actions:

- Play Fair: Establish and clearly communicate learning objectives and assessment practices; when possible, include students in curricular decision making.
- Care: Respect and support students in academic and nonacademic ways.

CHILD ABUSE

Child abuse is a serious social issue that causes harm and results in the death of children every day throughout the United States and the world. It is both a psychological and an educational issue that affects individuals, families, schools, and communities, resulting in both immediate effects and long-term serious consequences on the lives of those it touches. This entry provides definitions, incidence of abuse, forms of abuse, characteristics of abusers, psychological effects on victims, and treatment interventions for both abusers and victimized children.

Definitions

Every state in the United States has a legal definition for child abuse and neglect based on the federal definitions cited in the Federal Child Abuse Prevention and Treatment Act of 1973 (CAPTA, 42 U.S.C.A. § 5106g) and as amended by the Keeping Children and Families Safe Act of 2003. Child abuse is defined as any act on the part of a parent, caregiver, or other individual that results in physical and/or psychological injury, or that can present a risk of serious harm to a child under the age of 18. Such acts include sexual abuse and sexual exploitation, and failure to act to protect the child if the abuse is witnessed. Neglect occurs when there is failure to provide for a child's basic needs for food, shelter, medical care, or appropriate supervision. Neglect includes failure to educate a child or attend to the child's educational needs, failure to provide psychological care, and knowingly permitting a child to use illegal substances (e.g., alcohol, illicit drugs).

Incidence of Child Abuse and Fatalities

The National Incidence Study of Child Abuse and Neglect (NIS) was mandated by the U.S. Congress to document and report on the incidence of child abuse and neglect. The most recent report, NIS-3 by Andrea Sedlack and Diane Broadhurst, covered a 7-year period and reported an increase in child abuse from previous years. Approximately 1.5 million U.S. children were abused or neglected during this period; physical abuse almost doubled and sexual abuse more than doubled. The most recent statistics available from the National Child Abuse and Neglect Data System (NCANDS) estimated 872,000 victims of child abuse in 2004; 1,490 of these were child fatalities (death of a child caused by injury from abuse or neglect); approximately 60% were victims of neglect, 19% suffered physical abuse, and 10% suffered sexual abuse. Children ages 4 or younger are most vulnerable because they are unable to defend themselves or seek help. Based on data from 32 states, 81% of the children who died were younger than 4, 11.5% were 4–7 years of age, 4.1% were 8–11 years of age, and 3.4% were 12–17 years of age.

The NIS-3 study identified factors that contributed to the highest incidences of abuse. These included the child's gender and age, family income, and family size. Race was not a significant factor found. There is little reporting of sexual abuse in children under the age of 3; however, the numbers begin to rise from preschool onward. Girls are more at risk for sexual abuse than boys; boys are more vulnerable to other forms of abuse that result in serious injury or death. Family characteristics contribute to higher incidences of child abuse. Children from single-parent homes have a higher risk of physical abuse and neglect than children living with intact families. Children who live in poverty or come from large families are more at risk of all types of child maltreatment.

Types of Child Abuse

Four major types of child abuse are recognized. These include physical, emotional, sexual, and neglect. These can occur separately, but often are found in combinations. Physical abuse results in a physical injury from acts such as severe beatings that can cause bruising, fractures, and death. Shaking, choking, throwing objects, kicking, burning, or other forms of physical acts constitute physical abuse. Punishment such as having children kneel for periods of time on stones or hitting them with belts or other objects is considered abusive.

Emotional abuse results from acts that include a continued pattern of degrading, denigrating, insulting, and ridiculing a child. It can include withholding affection and support, rejecting, terrorizing, and isolating the child from others. Some consider emotional abuse to be more detrimental to the child because it can have long-term psychological effects on self-esteem and psychological development.

Sexual abuse is sexual manipulation or coercion by an authority figure. It includes incest, rape, molestation, performing indecent sexual acts in front of children, exposing them to sexually explicit materials, photographing them in sexual explicit poses, and/or sexually exploiting them for prostitution.

Neglect is evidenced by the failure to provide adequate nourishment and by creating a living environment that is consistently dirty and unkempt. There is apathy on the part of the caregiver to provide for the child, and these children come to school disheveled with torn and soiled clothing. They are often left unsupervised, and their medical, psychological, and educational needs go unmet. Often, there is little or no affective stimulation or warmth, and in the case of infants, no nurturing or proper hygienic care is provided. Some victims of abuse have suffered multiple forms of abuse. For example, at times, sexual abuse may involve physical abuse, and a neglected child is most likely also emotionally abused.

Cultural Influences

Child abuse and neglect occur in all cultures and ethnicities, and on all socioeconomic levels. It is found in every country in the world. In some cultures, traditional values support the concept of physical punishment and the ridicule and humiliation of children for undesirable behaviors. What may constitute child abuse in the United States would not be considered so in other countries, especially in places where exploitation of children in the labor market, in war, or for sexual purposes is tolerated.

In the United States, African American, Pacific Islander, and American Indian or Alaska Native children have the highest rates of victimization; Asian children the lowest rates. According to the Child Maltreatment Report of 2004, White children were the most victimized at 53.8%; 25.2% were African American and 17% were Hispanic. Children with disabilities accounted for 7.3% of all victims. Parenting children with disabilities can increase the stress level for parents and caregivers, potentially placing these children at higher risks. Parental stress increases because these children can be more difficult to care for, have behavioral problems, have limited communication or mobility, and require constant attention and supervision.

Child Abuse in Schools

Child abuse is most associated with dysfunctional families; however, it does exist in our nation's schools. Some children experience their first incidence of abuse by teachers in schools. When abuse is observed in schools, it is sometimes left unreported by teachers and principals. Children often will not report experiences of abuse to teachers or other school professionals because they believe that nothing will be done about it. When they do report, they will disclose to peers or family members. It is critical for educators and school administrators to report disclosure of abuse by children and for school districts to have written policies on reporting procedures. In most states, educators who fail to report incidences or suspicions of abuse are subject to fines or other legal consequences, so professional development training for teachers and other school personnel is essential to help them understand signs and symptoms of abuse, reporting guidelines, and interventions.

The Abusers

There is no specific profile of an abuser, although various characteristics have been identified over time. Perpetrators of child abuse are defined by most states as parents or other caregivers such as relatives, babysitters, and foster parents. According to NCANDS's most current report, *Child Maltreatment 2004*, of the

872,000 child abuse victims, parents were the abusers in 78.5% of the cases; 6.5% were relatives; 4.1% were unmarried partners of parents; and the remaining were residential facility staff, child care providers, legal guardians, and foster parents. More than half of these perpetrators neglected their children, 10% physically abused them, and 6.9% sexually abused them. Fifteen percent committed more than one type of abuse.

Often, the perpetrators are young adults in their mid-20s living below the poverty level and lacking a high school education. They have difficulty coping with the stresses of daily living, and in some instances were abused themselves as children or were exposed to family violence. Family environments where these factors are present are more likely to expose children to frequent arguments, parental fighting (sometimes physical), and situations where children live in conflict and fear of violent reactions from their caretakers. Furthermore, parents and caregivers who themselves suffer from depression, personality disorders, substance abuse, or other emotional disturbances are more likely to abuse their children. Teenage parents who lack resources such as financial and social supports to care for children may also be at increased risk of abuse. Parents who are prone to act violently and who lack empathy perceive the world differently and may be more predisposed than others to be abusive to children.

Fathers tend to be the cause of the majority of child abuse fatalities resulting from physical violence, whereas mothers were most often responsible for neglect. Although parents tend to be the main perpetrators of aggression toward children, siblings and relatives living in the family environment can also physically, emotionally, and sexually abuse them.

Psychological Effects on Victims

Abuse is about control and power over another person. The psychological effects of abuse on victims will vary depending on the type of abuse endured, the length of time the abuse occurred, and the intensity of the abuse. A single abusive event can create Type I trauma, whereas repeated and prolonged abuse in children who endure severe pain, torture, consistent violence, and family conflict experience Type II trauma. Type II trauma has more debilitating effects on children. Children who experience Type II trauma develop coping mechanisms such as dissociation, denial, and shifts in mood from anger and rage to extreme passivity and withdrawal. Educators and human service professionals, when observing abused children, must consider the above factors and the extent of the trauma to better understand and treat symptoms and behaviors. Not all children will act the same. Some children will internalize the trauma and can be observed withdrawing and appearing sad, depressed, and lethargic. They may be fearful of others and avoid interactions. They may engage in somatization and exhibit physical symptoms such as headaches, stomachaches, or other ailments. They may exhibit self-mutilating and suicidal behaviors. Those who externalize the trauma will express their anger and rage toward others or animals. For example, they are prone to violence and hostility, and they may kill or torture animals or destroy property. In cases of sexual abuse, these children may demonstrate sexually provocative and explicit behaviors.

Effects of Physical Abuse

Physically abused children lack a joy for life. Depending on the extent of the abuse, they may have been removed from their homes and put in foster care or have endured multiple hospitalizations. In cases of severe physical abuse, these children may have physical impairments in speech, language, and motor functioning. They feel abandoned and rejected by their families. In school, they can exhibit academic and learning difficulties and rebelliousness, and have problems easily establishing friendships with other children. There may be physical consequences, such as bruises, burns, scarring, and broken bones. Abused children may suffer from depression and withdrawal, or may physically act out toward authority figures and peers.

Effects of Emotional Abuse

Emotionally abused children experience loss of self-esteem and often feel isolated and disengaged from others. They may become hypervigilant and suspicious and appear to be always on guard. In school, they may act belligerent toward teachers and may engage in hitting and fighting with other children. They are less motivated to attend school and complete academic assignments. Those who internalize the trauma will not engage in play or social activities and appear passive and nonresponsive to external stimuli. They can be moody and fearful of expressing feelings.

Effects of Sexual Abuse

Children who have been sexually victimized will exhibit an array of symptoms and behaviors that can run on a continuum from few symptoms to engaging in prostitution or becoming sexually predatory toward others. The behavior of these children depends on the severity of the abuse, the relationship to the perpetrator, the frequency and intensity, as well as the support from family members following disclosure. Common symptoms include depression, low self-esteem, anxiety, substance abuse, posttraumatic stress disorder, and self-destructive behaviors such as suicide and prostitution. These victims feel shame, embarrassment, and guilt. In extreme cases of repeated, prolonged sexual abuse, dissociation occurs as victims experience a sense of hopelessness and helplessness. When dissociating, the child copes by detaching from the self and the act that is being committed. A loss of identity and memory difficulties can result. These victims, because of their exposure to manipulated sex, become sexualized and will display overt sexually provocative behaviors, abnormal preoccupation with sex, and a lack of inhibition toward sexual acts or sexual conversation. Child abuse victims are at a higher risk for sexually transmitted diseases, pregnancy, and prostitution. They will have continued difficulty engaging in normal intimate and sexually rewarding interactions in adulthood.

Effects of Neglect

Victims of neglect have experienced a lack of, or no, nurturance and attention from parents or significant others. These children will suffer many of the same psychological effects as those who have been physically or emotionally abused. They will experience loss of self-esteem, abandonment, lack of affect, and difficulty expressing emotions. They tend to have a negative view of the world and may suffer from anxiety, depression, or overly aggressive behaviors toward others. They are often cognitively developmentally delayed. They feel no one cares for, and about, them and also experience a sense of hopelessness and helplessness to seek resources on their own.

Child Abuse Reporting

All states have designated agencies for the reporting and investigation of child abuse incidences, which then report these data to a central registry for tracking purposes. Specific state statutes require mandatory reporting of suspected child abuse. These statutes require certain professionals who work with children, such as educators, social workers, therapists, physicians, nurses, and law enforcement personnel, to be mandated reporters of suspected child abuse and neglect. Failure to adhere to these statutes can result in fines and legal charges, including felony charges and potential jail time. These professionals are believed to be in a unique position to observe instances of child maltreatment that might otherwise go undetected. Should a report be necessary, these professionals should inform the nonabusive parent that a report will be made.

If a minor child (client) discloses abuse, he or she should also be informed that a report will be made for his or her protection. Helping the victim deal with social service agencies and other authority figures who will be investigating the case and discussing the process is recommended. Early detection and reporting of maltreatment are critical in reducing further harmful effects to children.

Prevention and Treatment

The first step in prevention is reporting suspected abuse so it can be investigated and a determination made as to the most appropriate services for a child victim and his or her family. Referral to appropriate service agencies following the report provides support and resources to the abused child and family. Treatment should be comprehensive in that many resources and treatment modalities for all family members are provided. It is not enough to treat the abused child; family members must also be included because child abuse and neglect are experienced by the entire family.

Prior to selecting the treatment approaches that will be used, an assessment of the family is crucial. It should be determined whether parents or caretakers themselves have had personal experience with maltreatment in their family of origins, and if they may be suffering from personality disorders or other emotional disturbances that would warrant psychiatric intervention. It is essential to gain an understanding of parental child-rearing skills and stressful situations and events, and how these have been dealt with in the past within the family structure. An assessment of the child is useful to (a) determine if there is a disabling condition that could add undue stress to the family, (b) identify any behavior problems the child may have

at home or in school, (c) determine the child's developmental level, and (d) identify the child's adaptive and coping abilities. Knowing the child-rearing values and traditions of the culture of the family is important so as not to misinterpret social cues and behaviors on the part of the child, caregivers, and other family members. Observing the interactions between the child and caregivers can provide insight into the child–parent relationship and response behaviors toward the child. Parents and caregivers who maltreat children will exhibit less positive and nurturing behaviors toward them. They will be less likely to interact with their children, may be prone to quickly admonish or criticize the child, may have higher expectations than nonabusive parents, and may make inappropriate demands on their children for their developmental level. Following assessment, when selecting treatment approaches to use, therapists must make decisions regarding whether to treat the entire family as a whole, the couple, the abused child, or the parent–child dyad, and what specific modalities will be used.

Treatment Interventions for the Abusers

A behavioral approach has been recommended for abusive parents and caregivers because this approach is more directive, problem and solution focused, and educational in nature, and it places the responsibility on the family members to take action and make changes in their behavior. This approach is also intended to help parents become more sensitive and responsive to their children's needs. Cognitive therapies have been used to help parents gain awareness of irrational and dysfunctional beliefs and to change these belief systems into more rational, logical thinking that will promote appropriate behavioral responses. Individual, family, and group counseling can be used simultaneously. Individual counseling for the child and individual family members can be conducted in conjunction with group and family counseling interventions. Group counseling is beneficial because it connects parents to other maltreating parents who can serve as support networks to one another. In groups, parents can learn appropriate child-rearing and parenting skills and where to obtain assistance and resources for their families. Parents who maltreat children will need to learn techniques to control and manage their anger on a daily basis. They will learn how to respond to their children without shouting, hitting, or using other aggressive forms of behavior. They should be taught methods they can use to manage

and handle stress such as deep breathing and relaxation techniques. These individuals must be provided with opportunities to discuss feelings of frustration, shame, guilt, and inadequacy with their therapists and with other parents who share similar concerns. Role-playing by the therapists and group members can help ease parental anxiety and provide a mechanism by which to practice desirable behaviors and obtain immediate feedback from others. The therapist may need to combine treatment modalities with periodic home visits to assess whether what is being learned in therapy is being transferred to the home environment. To help abusive parents become more self-reliant, connecting abusive parents with sources of social support is necessary. These support venues include community agencies that can assist with housing, health, and social needs; churches or other religious organizations; day care providers; and employment counselors who can provide parents with resources to find better jobs or obtain training. Extended family members and friends can help provide emotional support and encouragement.

Treatment Interventions for the Victims

Treatment approaches for child victims will depend on the severity of the abuse the child has experienced. In addition, in order to be effective, the types of treatment selected must be congruent with the child's developmental level and symptoms. To protect and provide a safe environment, children are sometimes removed from the home and placed temporarily with relatives or in foster care. Therapeutic day care treatment has been used to increase the child's developmental and social skills and as a protective measure. The rationale behind the use of these two approaches has been to provide a hiatus for the family so they can participate in therapy before the child is returned home or adopted by another family. The intent has always been for this approach to be short term, but fewer than 40% of foster children ever return after 2 years in foster care. Furthermore, it is becoming increasingly difficult to find suitable foster care facilities for children, and many children shift from one home to the next and are separated from their siblings. Many abusive parents are never totally rehabilitated, nor do they respond to treatment positively, and they continue abusive patterns of behavior.

Child victims who experience severe trauma and suffer from symptoms of posttraumatic stress disorder are treated with education that involves teaching them

how to cope with stressful situations. Play therapy, the use of expressive arts and writings, and person-centered approaches that provide a means by which to express repressed feelings have been used. Experienced clinicians, in controlled settings, can also help the child recall memories of the traumatic event and work through feelings of anger, hurt, anxiety, shame, and distrust. This is especially critical for sexually abused children who have repressed memories of sexual exploitation and abuse.

Future Considerations

Child abuse is a social, educational, and psychological problem that occurs at epidemic proportions in the United States. It is a problem that warrants more attention than it has received in the past, both in the United States and abroad, because of the impact such abuse has in childhood and adult years. Education is needed to assist helpers and human service professionals identify signs and symptoms of abuse and to follow legally mandated reporting procedures. Treatment interventions aimed at helping both the abusers and victims effectively cope with the psychological factors resulting from abusive patterns of behavior and victimization are needed. Preventive measures, such as parenting skills classes and stress and anger management techniques, must be provided on a continuing basis by human service providers so as to educate others and to prevent abuse before it occurs. Efforts at prevention of child maltreatment are necessary in order for this epidemic to be thwarted.

CLASSICAL CONDITIONING

Classical conditioning (also named *Pavlovian conditioning*, for Ivan Pavlov, the researcher who pioneered the topic) is considered, along with habituation, to be a fundamental form of learning. The term *conditioning* is used because classical, along with instrumental and operant, is considered a simpler and more basic form of learning. As a form of learning, classical conditioning involves a relatively permanent change in behavior potentiality that arises as a result of particular experiences. Hence, at one time a certain behavior does not take place. But as a result of independent variables (or imposed stimulus contingencies), a particular target behavior then does take place with greater probability.

Unlike habituation, which involves only a single stimulus, classical conditioning involves two stimuli that are paired. The purpose of one stimulus is to reliably elicit behavior. This is the *unconditional stimulus* (or US, because it will provoke a response unconditionally), also called *unconditioned stimulus* (because the response to it did not have to be trained). It elicits the unconditional, or unconditioned, response (UR), which is already in the organism's repertoire. The other stimulus—the *conditional stimulus* (CS), because the response to it is conditional, or *conditioned stimulus*, because the response to it must be learned—is neutral with respect to the US. The CS, in order to be a stimulus, must evoke some response; but that response, or pattern of responses, is unrelated to the US, and hence, those responses have little or no similarity to the UR. If training is effective, then the CS has acquired some capacity to elicit a response that resembles the UR. But because it is elicited by the CS alone, it is considered a learned response—a conditioned (learned), or conditional, response (CR).

Training consists of pairing CS and US, ideally with CS onset preceding US onset on each trial. So, initially, before conditioning, the CS provokes little or no conditioned response, which serves as a baseline for evaluating the amount of learning reflected in the amount (percentage, magnitude, probability) of CR following training.

All of the basic phenomena that take place in learning paradigms (to include instrumental, operant, and habituation) are found in classical conditioning. As in other paradigms, acquisition occurs as a negatively accelerated function, meaning that the greatest behavior change takes place during early trials. A practical implication is that those initial trials are rather crucial because this is the time when errors are readily mastered, and considerable training will be needed to extinguish those flawed behaviors. Another implication arises later in learning when performance is nearing asymptote. As a curve of decreasing returns, less and less additional change in performance (reflecting less and less further learning) is observed with additional training trials. (Good examples of these considerations are found in learning physical or sport skills. During initial training, mistakes can be learned quite readily—pointing out the importance of guidance and error-free training for novices. Later, highly skilled performers have difficulty maintaining motivation to keep working when

their efforts seem to show very little payoff.) The other basic phenomena include such matters as extinction, spontaneous recovery, stimulus generalization (positive transfer), stimulus discrimination, external inhibition, disinhibition, and so on.

A great deal of research has been conducted dealing with time relations between CS and US presentations and characteristics of stimuli (e.g., intensity and complexity). It is quite clear that for optimal conditioning, the CS onset should precede US onset—the time between onsets being commensurate with the latency of the UR. For a very simple and quick response (e.g., eyeblink, which is popular in much of the animal research), roughly 0.5 seconds seems optimal, whereas for a slower or more elaborate response, some number of seconds would be suitable. In essence, the CS is functioning as a signal that forecasts the presentation of the US. So, it appears as though there needs to be sufficient time for the CS to allow the learner to prepare for the US, and to anticipate it. When it comes to stimulus intensity, it appears that US intensity is of particular importance. It must be "prepotent" in that it is strong enough to take priority, dominating over other stimuli that could cause distraction or evoke behavior that could compete with and weaken the UR. The function of the US is to evoke a particular pattern of behavior, so it makes sense that a strong and unambiguous elicitor is desirable. A weak US will evoke a weak UR or a UR that could be viewed as "sloppy" in the same way that unclear and ambiguous guidance or instruction leads to behavior that is not clearly on target. With classical conditioning, the behavioral outcome is thoroughly in keeping with the behavior evoked with the US. Or, in other words, "what you do is what you learn." It should be noted that a US need not be appetitive (evoking behavior that fits a general category of "approach") but can be aversive (leading effectively to avoidance behavior).

Higher intensity may be of some importance for the CS—but within reason. An excessively strong signal can provoke some behaviors that can interfere with both CR and UR. It has been suggested that any stimulus above threshold (detectable) can serve effectively as a CS (as long as it reliably predicts occurrence of a US)—meaning that learning can take place with very subtle cues. But to have an optimally effective CS, it would appear that not just adequate intensity is important but greater complexity is of considerable value. Note that complexity does not mean difficulty; rather,

it means number of elements. So, when signals are important, they include many components (e.g., a railroad crossing in a high-traffic area or warnings about fuel and altitude in aircraft cockpits will have a variety of visual features plus sound). Typically with compound stimuli, a particular element will be dominant; sometimes, that element will overshadow the others. But typically, the "weaker" elements will add and contribute to the overall signal value.

Classical conditioning can easily be regarded as a substrate in that it can be seen as a basis or underlying process in instrumental and operant conditioning. It also has rather obvious roles in those paradigms whenever some learned element is involved. For example, secondary reinforcers (also appropriately called conditioned reinforcers) are extremely powerful and practical tools for instrumental and operant conditioning. Perhaps the ultimate example is clicker training for dogs and other animals, where the sound of the clicker (which serves as the secondary reinforcer) had been paired with some incentive (dog treat), but can now serve to "reward" the animal immediately following some target behavior. Virtually all of the social reinforcers for humans (smiling, nodding, attention) can be seen as having acquired their incentive value in analogous fashion. Discriminative stimuli in instrumental and operant conditioning serve as signals that have been associated with particular contingencies rather than specific stimuli.

Finally, in practical application, classical conditioning is often where some form of training begins as a way to establish some behavior. And once some behavior is stable and reliable, it can be used for building additional outcomes. For example, with higher-order conditioning, an established CS can function as a US. Furthermore, it probably rarely maintains a "pure" form but becomes combined with or replaced by instrumental contingencies and incentives. For example, if a parent is teaching vocabulary, the parent may prompt by saying, "Say ball." After a few of these trials (US-UR), the parent may hold up a ball, point to it, and say, "What's this? Say 'ball.'" Then, the parent may fade out the US, eventually presenting the CS (pointing to the ball and saying, "What's this?"). When the child emits the CR of "ball," then the parent may respond with a social reinforcer: "That's right; good for you." It could be argued that classical conditioning should be seen as the substrate and underlying process for most of our learning. Indeed, most of our vocabulary and nearly all our emotions (preferences as well as fears) can be attributed to classical conditioning.

CLIQUES

Relationships outside the household become increasingly important as a child moves through adolescence. One way to view these relationships is through cliques, which can be defined in two ways: (1) Researchers define a clique as a grouping of persons who interact with each other more regularly and intensely than others in the same setting (a more neutral definition), and (2) the more popular definition by laypersons is a social grouping of persons that exhibits a great deal of peer pressure on its members and is exclusive, based on superficial differences (a more negative definition).

No matter which definition is chosen, cliques exhibit common criteria. Cliques are a small social group of anywhere between 2 and 12 persons, typically averaging around 6. They are created based on similar characteristics of their members, including age, gender, race, social status, socioeconomic status (SES), and shared interests and activities. Cliques provide the major social context in which youths interact with each other, and thus are of high importance for their healthy development.

Along with the definition, an important distinction must be made to separate cliques from the similar peer grouping of crowds. Crowds are a larger grouping of individuals who share a common image or reputation with each other, or may have similar features (race, SES), but do not necessarily accept their membership in said group. Examples of crowds are jocks, nerds, populars, cheerleaders, and so on.

This entry describes the formation and maintenance of cliques, including gender differences, changes in clique structure across adolescence, types of individuals

in/out of cliques, the process of joining cliques, as well as the benefits and problems with cliques.

Gender Differences in Cliques

Although many similarities exist between male and female cliques, they do have some important differences. Females are more likely as a whole to become members of cliques, whereas boys are more likely to be nonmembers. Females are also more likely to form cliques at an earlier age than boys, with females beginning around age 11, boys at 13 or 14. Female cliques are more focused on vocal activities, including gossip and sharing thoughts and feelings, and are easily hurt by the gossip and hurtful remarks spread by these cliques. Male cliques are typically focused around similar activities and interests. Research has also found that males have a greater desire for acceptance from a group, and more concern with status than females, who were more interested in being emotionally closer to a smaller group of peers.

Changes in Clique Structure Over Time

It has been stated that the structure of cliques develops in parallel to the development of identity; thus, important changes are seen as youths move through adolescence into adulthood.

Preadolescence

Preadolescence marks the initiation of cliques as youths begin to separate from familial relationships being of primary importance. These early cliques are created almost entirely of same-sex individuals and are formed around similar interests and activities rather than other demographic characteristics.

Mid-Adolescence

Mid-adolescence involves great changes in both clique structure and activities, as youths become more interested in the opposite sex, but do not yet have dating relationships. This is a time in which cliques become more segregated based on demographics beyond sex and interests/common activities. Cliques begin to integrate at similar venues with opposite-sex cliques, but their membership does not yet change. Later, as youths become interested in dating relationships, cliques begin to open up to mixed-sex and even mixed-age membership.

Late Adolescence

As youths begin to enter late adolescence, dating relationships begin to take precedence over clique membership. Cliques begin to collapse as members are lost and are replaced with pairs of dating adolescents. These pairs form loosely associated cliques, which separate from the larger group activities in favor of individual ones. This form of clique structure is said to extend into adult relationships.

Types of Individuals in and out of Cliques

Through the use of observation studies, researchers have identified three types of youths in clique membership: clique members, liaisons, and isolates.

Clique Members

Clique members comprise fewer than half of all adolescents, and are actively a part of a single, small group of persons. They spend most, if not all, of their social interactions with these same individuals.

Liaisons

Liaisons are individuals who interact with some members of a clique, but not with all. Liaisons can associate with multiple separate cliques, and are generally well thought of by their peers. This type of individual comprises approximately 30% of youths.

Isolates

Isolates are individuals who are not involved with any clique members, and generally have few, if any, relationships with peers in their social network. Isolates may be of volunteer status, in that they actively avoid relationships, or they may be of forced status (also labeled as targets or victims), in which they are set up by others to be excluded and ridiculed.

Joining Cliques

Because of the hierarchical interior structure of cliques, some individuals who desire membership are denied. This membership is maintained through

a careful screening process, usually established and maintained by the leader. Two methods for obtaining membership exist: invitation and application.

Invitation

Invitation into a clique can occur as a direct request from one of its current members or by indirect socialization. Indirect socialization can resemble an advertisement of what the clique can offer the prospective member, involving a courtship attempting to show how great life in the clique actually is. Also important (with application as well) is that before this potential new member is invited/accepted, the leader(s) of the group must desire his or her membership; however, if the leader(s) of the clique want to give someone membership whom the other members disapprove of, the person may still receive an invitation/acceptance with little effort from the leader(s).

Application

Application is the second way a person can be granted entry into a clique, which may not appear much different from the outside looking in, where a similar courtship will exist. Also important is that although application may not be immediately made through the leader (applicants may begin to socialize with lower-level clique members), nearly all applicants will end up attempting to impress the leader(s) before acceptance is granted.

Status and Hierarchy of Cliques

Maintaining Status

Cliques have a very strong hierarchical status structure inside them, containing at least one leader (typically a single person reigns). This status structure can also be quite transient, and changes in status are likely to occur regularly. It is said that members need to be constantly working to hold on to, or increase, their position in the clique. For leaders of cliques, this can become a harsh process, which has led many to hold a negative view of cliques. One way in which a leader maintains his or her status is to alternate praise and criticism toward other members, which keeps the leader from gaining negative attention on him- or herself. Leaders may also change the way the clique views activities, values, and/or opinions of things to keep the other members unsure of where

they stand in the group. Beyond these changes, clique members constantly change friendships so as to socialize with only the most popular of peers.

Types of Group Members

In her book *Queen Bees & Wannabes: Helping Your Daughter Survive Cliques, Gossip, Boyfriends & Other Realities of Adolescence*, Rosalind Wiseman describes her observations of cliques and groups female adolescents into several roles:

Queen Bee: The leader of the group, who Wiseman describes as ruling by "charisma, force, money, looks, will, and manipulation" (p. 25).

Sidekick: The lieutenant of the clique, who is said to have no voice but that of the Queen Bee, consistently backing her up no matter what the issue.

Banker: The girl who holds all of the information and gossip, and releases it for her own benefit.

Floater: Similar to the liaison described earlier, a girl who can go in and out of more than one clique.

Pleaser: This person can be in or out of the clique; she will consistently back up the Queen Bee and the Sidekick, but receive very little credit for doing so.

Target: Typically outside the clique, this person is excluded by the members and humiliated on a regular basis.

Male Roles

Although Wiseman's book centers around the lives of female teenagers, she also adds a section for males, and describes their similar roles:

Leader: Similar to the Queen Bee, Wiseman describes him as, "Everyone wants to be him … athletic, tough, able to get the girls, or rich" (p. 183). Contrary to the Queen Bee, he is typically well respected.

Flunkie: Similar to the pleaser, in that he will do anything asked of him, but different in that he responds to any member. This person constantly gets into trouble and irritates others because of his actions.

Thug: Can also be a wannabe thug. This person is smarter than he lets on and typically communicates in nonverbal bullying behavior. Although this person appears popular, he may or may not be.

The Get Wits: The groupies of the male clique. These males are well respected by adults for being good, but

their peers do not hold them in similar respect. and they are seen as tagalongs.

Hierarchy of Cliques in Social Setting

Not only does a hierarchy persist inside of cliques, but a hierarchy also ranks cliques belonging to the same social network. Similar to the hierarchy and status maintenance that occurs inside of cliques, there are also changes to the clique rankings; however, this status rank does not change as frequently as internal statuses. Although cliques differ from crowds, these larger peer groups can play a large role in the status of a clique. The more popular the crowd with which members of the clique identify, the higher the status of the clique, and multiple cliques identifying with the same crowd will be more likely to have status fluctuations with these similar-status cliques.

Benefits and Problems With Cliques

Benefits

Although cliques are typically seen as a negative force on adolescents, they do have some positive attributes. One such attribute involves the development of social identity. Through the formation of peer groups such as cliques, adolescents learn to identify types and regulate social interaction. Adolescents begin to see themselves as others perceive them, and they are taught through these interactions to control their emotions and behaviors.

A second benefit of cliques is that they can help promote an adolescent's self-worth. Research has shown that they provide a strong effect on this important feature of self-esteem. As stated earlier, adolescents begin to see how others perceive them through peer groups, and the perception of others has been found to have a large impact on how a person views him- or herself.

Problems

The benefits with cliques can also easily become problems. With regard to the development of social interaction, adolescents in overly competitive cliques can perceive all social networks as being this way, and thus act in a way to compete with others. With self-worth, adolescents can easily develop negative perceptions of how other people perceive them, or they may see the constant changes in status and think

that they are worthy only if they have something to offer or if they push other people down.

For better or for worse, peer groups such as cliques are the most prevalent friendship structure in adolescence and thus produce a strong effect on adolescents' further development.

COGNITIVE AND CULTURAL STYLES

The unique ways in which students learn and teachers teach, or learning and teaching styles, are closely related to cultural values and personality types. Matching preferred styles can prevent school failure, enhance success, and motivate students to stay in school and develop talents to their fullest. Matching students' preferred styles can also make the teaching experience more satisfying for educators and can increase the effectiveness of educational programs. However, as American society becomes more complex and diverse, schools and teachers are finding it more difficult to identify and match the preferred cultural and cognitive styles of students.

Cultural styles reflect virtues and philosophies of life that are emphasized by families, communities, and cultures. As one component of learning styles, they serve as guideposts or markers that children use as they move through life in search of the careers and the life goals they find meaningful and fulfilling.

A second major component of students' unique learning styles and teachers' instructional styles is cognitive styles. These are styles of personality that determine how students like to learn, the ways in which they prefer to relate, the types of rewards that make success in school meaningful, the preferred manner of communication, and leadership style. Cognitive styles are related to cultural styles through the process of socialization and instruction by parents, other authority figures, and cultural experiences in the home and community.

By the time children attend school, they have developed specific cultural and cognitive styles that are related to how they like to learn and how they process and retain information. These cultural and cognitive styles may or may not be compatible with their instructors' teaching styles and the cognitive and cultural styles emphasized by the schools they attend. Some cultures and families emphasize emotional IQ, or the importance of understanding people and relationships, and emphasize being a helpful and spiritual person who is a contributing member of a family and society. Instruction by adults is largely done by modeling and demonstration while simultaneously discouraging deviation from set practices and procedures. Other families and cultures tend to emphasize the value of traditional educational skills such as reading and math, and the importance of the individual is emphasized over that of the group. Instruction in these families is largely transmitted through trial-and-error learning where the child is encouraged to learn and to work independently of adults.

This entry focuses on how teachers, schools, colleges, and universities can become more sensitive to the preferred cultural and cognitive styles of students regardless of familial and cultural background. It is argued that the ultimate goal of education should be to identify the uniqueness of learners, and to individualize instruction in order to match the individuality of expression in learning environments. Specifically, the goal should be to match preferred student styles and worldviews in order to ensure enthusiasm for learning and success, thereby enhancing the adaptability and flexibility necessary to live happily and meaningfully in a diverse society and a global world.

Cultural Styles

Manuel Ramirez and Alfredo Castaneda's theory of cultural and cognitive styles flexibility proposes that cultures, communities, and families hold certain belief systems and perspectives on the meaning of life, identified as cultural styles, which can be classified on a traditionalism-modernism continuum. Bicultural or multicultural styles are considered to represent a combination of traditional and modern views. Examples of three major dimensions of traditional and modern styles are presented in Table 1.

The traditional-modern belief systems dichotomy was introduced by Robert Nisbet to conceptualize a conflict in societal ideology that emerged at the end of the 19th century. The conflict was given form by the democratic revolution and the Industrial Revolution. These worldviews define different perceptions of reality. Presently, the conflict has become more acute during the past two presidential elections and may be thought of as the genesis of dialectically opposed sets of values and goals. For example, the view of creation of the universe has been couched recently as intelligent design, or creationism, versus evolution. Another example is the perspective of the primary life goal, characterized by some as seeking salvation in the afterlife and by others as attaining meaning and fulfillment in the present life. Another way of understanding how cultural styles influence individuals is the measure of a "good" person. In some literature, it has been presented as emotional IQ and sense of community, and in other literature, it is presented as a more individual orientation to life.

Cultural styles are transmitted or moderated through socialization and the educational practices of parents, communities, and cultures. By the time children first encounter educational environments, they have developed preferred cultural styles that either match or do not match the preferred cultural styles of teachers, as well as the educational practices and programs of the schools they attend. The degree of match, in turn,

Table 1 Traditional and Modern Cultural Styles

	Type of Belief	
Focus of Belief	*Traditional*	*Modern*
Creation of the universe	Sacred	Rational
Primary life goal	Salvation	Living life to the fullest
Characteristics of the "good person"	Caring and compassionate "role model"	Self-determination or freedom to pursue life goals

determines the child's quality of adjustment and general success in learning environments. Flexibility in teachers and educational environments is essential to ensure student enthusiasm for learning and success in school.

Cognitive Styles

To ensure student success in educational settings, it is important to match their cultural styles and their personality styles. Educators are encouraged to become sensitive to the manner in which students approach new learning situations and to their motivation to learn. The type of relationship students prefer to have with teachers is also important, as is the types of rewards that encourage learning and retention.

Cognitive styles have five major components: relational styles, communication styles, motivational styles, learning styles, and teaching and supervisory styles. The three major cognitive styles identified by Ramirez and Castaneda are as follows:

1. *Field independent*—this personality style is characterized by a formal manner of relating to others (including both peers and teachers), a communication style that is impersonal and brief (economical use of words), a motivational style that is oriented toward achievement for the self, a learning style that is analytical and focused on the details of what is to be learned, and a teaching-supervisory style that encourages learning by discovery and trial and error.

2. *Field sensitive*—this style is characterized by a tendency toward a more personal and informal style of relating to others; a communication style that is more personalized and detailed; a motivational style that is driven by social rewards, especially praise from teachers and peers; a learning style that is more relational, with a tendency to merge knowledge from different fields or different sources; and a teaching-supervisory style that emphasizes modeling and mentoring.

3. *Bicognitive*—this last style is characterized by the ability to switch personality and cultural styles depending on the learning challenge or situation encountered. This style encompasses creativity as the ability to combine features and characteristics of both field independent and field sensitive personality styles to develop new approaches to problem solving. A bicognitive student has the ability to apply a combination of insights from different disciplines and the flexible use of analytical and relational thinking styles.

Some examples of some classroom behaviors related to field independent and field sensitive styles are presented in Table 2.

Research on development of individual differences in cognitive styles indicates that socialization practices play a key role in determining learning behavior preferences in children. The teaching styles of parents and other family members and the types of learning behaviors encouraged in families seem to contribute to the development of preferred learning behaviors in

Table 2   Learning Behaviors

Instructional Relationship to Teacher

Field independent	1. Likes to try new tasks without teacher's help
	2. Seeks nonsocial rewards such as gold stars
Field sensitive	1. Seeks guidance and demonstration from teacher
	2. Seeks rewards such as praise, which strengthen relationship with teacher

Thinking Style

Field independent	1. Focuses on details and parts of things
	2. Likes discovery or trial-and-error learning
Field sensitive	1. Focuses on the global nature of concepts of ideas
	2. Prefers discovery of concepts in humanized, personalized, and story format

children. For example, one family may emphasize the importance of people, such as how people relate to each other and their respective roles in the family. The child in this family may learn about motivation and about why people do certain things in certain ways. For this student, a close interaction between teacher and learner is encouraged. These children may learn many things by modeling what they see older people doing. These children develop the skills of what has been come to be known as emotional IQ.

Another family may encourage their child at an early age to find things independently. Children from such families may have learned to work out problems by trial and error. They will enjoy experiments with new materials and new games, but may not enjoy learning concepts requiring careful and exact observation and imitation. They may not learn to feel like they are part of a group as early as children from the family described previously.

Encouraging Development of Cultural and Cognitive Style Flexibility

The cultural and cognitive flex model applies the philosophy of cultural and individual democracy to educational environments. Horace Kallen introduced cultural democracy in response to the concern expressed by some segments of American society that some immigrants were slow at becoming Americanized. Observing a continuing persistence of languages, values, and lifestyles associated with nations and cultures of origin, Kallen suggested that it was necessary to adopt a cultural democracy perspective rather than a melting pot ideal for American society. That is, rather than insisting on forced enculturation to the American way of life, cultural democracy, derived from the idea of political democracy, would allow development of flexibility of beliefs and ways of life. It would give citizens the option to remain identified with their culture of origin while they adopt mainstream American culture. What Kallen proposed was an alternative to the melting pot; an opportunity for the development of bicultural or multicultural orientations to life.

Ramirez and Castaneda proposed that if cultural democracy were applied to education, it would facilitate the development of cultural and cognitive style flexibility in students regardless of ethnic origins. Specifically, cultural democracy was perceived as a philosophical precept that recognizes that the way a student communicates, relates to others, seeks support and recognition from his or her environment, and thinks and learns is a product of the value system of his or her home and community. When students are allowed to use their preferred cultural and cognitive styles, they achieve success and can proceed to learn their nonpreferred learning style. Through this process, students become bicultural and bicognitive. They become Americanized, but they also retain their identities with their original cultures. Individual democracy in the context of education, introduced by John Dewey, concluded that a society that constricted individuality would lose sight of democratic principles. He emphasized that public policy should respect whatever is unique and distinctive in each individual.

Research by Ramirez and Castaneda and also Barbara Cox and Ramirez found that most students have personality types that are bicognitive to differing degrees. Most learners, however, have a preference for one or the other style. By observing children in classrooms and college students in different learning environments and social and work settings, results showed that the degree of success in education and in life in general depends on their degree of bicognitive functioning. The researchers concluded that the ultimate goal of education was the promotion of flexibility in cultural and cognitive styles resulting in development of the total person.

To promote flexibility in cultural and cognitive styles, it is necessary to individualize instruction by encouraging flexibility in teachers and educational environments. Changes were suggested in four major components of instruction:

1. *Teacher training to enhance understanding of diverse cultural styles in American society.* Specifically, teacher training programs need to present the sociological, psychological, and anthropological characteristics of the different ethnic groups in this country. The information needs to be presented in an educational perspective. For example, cultures that are more traditional tend to teach by modeling and direct instruction, whereas more modern cultures generally teach by trial and error using a less directive approach. Teachers could be trained to use culture-matching teaching strategies and could learn how to assess the preferred cultural and cognitive styles of students. Teachers also need to perform self-assessment to become aware of their own preferred cultural styles and their relation to teaching styles.

2. *Development and selection of different kinds of curricula to facilitate learning among children with different cultural styles.* The principal focus of curriculum development should be on how new material is introduced and presented such that it incorporates cultural and cognitive styles. For example, if the lesson plan calls for teaching about rainbows, allowing children to tell stories about their experiences with rainbows is likely to be meaningful to those from traditional cultures. On the other hand, children from modern cultures might prefer experimenting with a bowl of water and a small mirror inside the bowl to capture sunlight to show how rainbows are formed. Both teaching strategies will benefit field sensitive/traditional as well as field independent/modern learners because they offer a diversity of teaching approaches that serves to match the preferred styles of each group while simultaneously providing the opportunity to add the nonpreferred skills to existing learning repertoires.

3. *Training teachers to use learning experiences and environments to teach respect for cultural differences and cross-ethnic cooperation.* This is particularly applicable in social studies curricula where the objective is to encourage students to understand familial, cultural, individual, and gender differences. For example, teaching about holidays celebrated by different cultures and discussing the lives of prominent women in society as well as the achievements of historical figures of different ethnic, religious, racial, gender, and socioeconomic backgrounds should be a part of social studies curricula. Teachers should also be taught to discourage use of ethnic and racial slurs and language that tends to disparage any group or person. Teachers should engage in proactive behavior to discourage ethnic isolation and should emphasize children of different genders and groups working together as a team to prevent isolationism and clique formation.

4. *Training for use of tests and other procedures for assessment of academic progress and intellectual ability to match the cultural styles of learners.* For example, children from traditional cultures are more likely to prefer essay-type questions or tasks that tap creative writing skills, whereas children from modern environments usually prefer multiple choice-type tests and assignment of projects that apply concepts to problems. The negative consequences of mismatch can have dire consequences for both learners and teachers because inaccurate conclusions can be drawn about the capabilities of students and the effectiveness of teachers.

Once instruction and curriculum content have been addressed, the students can then begin the match-mismatch process. The cultural and cognitive flex model of education follows three instructional steps: match of preferred cultural and cognitive styles, initiation of mismatch through match, and continued match and mismatch to promote flexibility and adaptability.

The first step acknowledges and respects the child's cultural and familial experiences in learning by matching the student's preferred cultural and cognitive styles. Assessment of the preferred styles of children when they first come to school is essential. Identification of the preferred cultural and cognitive styles of each child is done through classroom observation of behavior in an environment that allows for freedom of individual expression of cultural and cognitive styles. Once assessment is completed, the child is placed in one of three groups where instruction will be matched to preferred styles. This is the initial match.

The second stage is to gradually introduce mismatch of styles once the child achieves mastery in his or her preferred style. This is done by introduction to a bicognitive-bicultural group in which the nonpreferred styles are presented through use of the dominant styles; for example, introducing individual competition through group competition by asking group members to focus on which member achieved the most points during the exercise. This approach benefits the field sensitive and traditional learner who is in the process of becoming more bicognitive and bicultural.

Upon mastery in this environment, children are then introduced to the third stage in the flexibility development process, which is placement in a group where the child is introduced to new instructional strategies. These strategies include exposure to learning and testing materials that are written and presented in the previously unfamiliar styles. For example, a teacher introducing the nonpreferred style who uses the discovery approach might proceed in this manner: "Yesterday, I showed you how to find out if two triangles are equal. I have also showed you how to find out if two squares are equal. Now you know the shortcut I use in finding out the area of something. I have some rectangles for you to look at, and I want you to find out if they are the same, but I want you to do it in the way you think I would, using the shortcut I used with the triangles and the squares." After becoming familiar with the mixture of cognitive and cultural styles, the child is ready for the transfer to the group in which teaching and curriculum are based almost exclusively in the unfamiliar style.

The fourth and final stage is progression into an advanced mixed-styles group in which both styles are used to reinforce maximum flexibility and adaptability. An example of a lesson plan that would be presented in this group is as follows: In a field independent math lesson, a child whose preferred cognitive style is field independent and cultural style is modern feels familiar with an abstract, impersonal curriculum. This student enjoys individual competition and learns most advantageously when the teacher emphasizes individual effort. In a field sensitive and traditional curriculum (based on the child's unfamiliar styles), the child easily makes the transition from a math lesson that emphasizes inductive reasoning and abstract concepts to one that emphasizes deductive reasoning and personalized/humanized concepts. This student can work just as well cooperating with classmates as competing with them in the field independent-modern math lesson.

The flexibility and adaptability that students develop can transfer to areas of life outside educational environments. They are likely to become more receptive to other languages and other cultures, giving them the opportunity to achieve linguistic and cultural flexibility.

To succeed in preparing students for success and good psychological adjustment in a complex and technological society, we must get away from the one-size-fits-all mentality that is presently so much a part of the American educational system. A focus on individualizing instruction and utilizing technology can make this possible. For example, a computer program can determine a child's preferred cultural and cognitive styles by assessing the preferred styles at the start of the school year. The program would teach a new concept by asking simple questions regarding preferences for content and strategies for learning. The program could also monitor the progress of the student through the steps of cognitive and cultural flex achievement. Each individual student's record can become a part of his or her educational history and used to plan his or her advancement through each grade. In addition, it could serve as a useful record for different teachers when students change schools or move from elementary through middle and high school.

The work by Ramirez and Castaneda and that of their colleagues focused primarily on Mexican American children, showing how the traditional cultural styles of Latino children were being mismatched by the predominantly modern styles of the American public school system. Mismatch between preferred cultural and cognitive styles and the teaching styles, curriculum, and educational procedures of schools can result in mismatch shock, defined as exhibiting stress and feelings of failure and alienation. To this day, mismatch is the major reason why Mexican Americans continue to have the highest dropout rate of any ethnic group in American society. The mismatch factor is also important for the high failure rate in other ethnic/racial cultural groups in the United States who are being mismatched by educational institutions, teachers, and professors. As reported by the *New York Times* in February 2007, even when some schools make the effort to introduce diversity in curriculum offerings, school boards may stifle the effort. In fact, all school-aged children and college students, regardless of race, ethnicity, or socioeconomic class, are likely to be mismatched and to become discouraged and frustrated. A recent study by the Education Testing Service found that high school graduation rates and achievement gaps in reading and math skills have not changed very much in the past 20 years.

Assessment and Testing

As testing has become an indispensable component of the American educational system, it has also become a barrier to individualization of instruction and to a culturally democratic education. Cultural and cognitive styles in students can be mismatched by standardized administration procedures as well as mismatch of the content and structure of the assessment instruments. Mismatch through testing can lead to inaccurate conclusions regarding level of curriculum mastery and general intellectual ability. These two issues have become salient in the past few years because of the emphasis on testing related to the No Child Left Behind Program. Teachers have been forced to "teach to the test" as administrators focus on school test performance scores for teacher evaluations, salary increases, and recognition. This forces teachers to remain with a field independent type of curriculum and teaching strategies, thereby overlooking individual and cultural differences in their students.

Ultimately, there is a double threat of mismatch: first, between the teacher and student, and second, between the teacher and the test-oriented curriculum. When teachers are forced to "teach to the test," opportunities for collaboration between children and teachers on creative classroom projects are lost. In one extreme, creative science or art projects, which

encourage comparing classroom work to real problems, are considered secondary to rote and mechanized drills. For example, when teaching about the weather, students could be encouraged to play the role of meteorologists who predict and chart weather patterns rather than just memorizing information.

Regarding procedures of administration for tests and evaluation instruments, research has found that field sensitive and traditional children do best under conditions in which the administrator befriends them and presents the testing situation as a game rather than the more formal and distant conditions usually suggested for test administration. Additionally, children who are mismatched by testing procedures and instruments can be barred from promotion or graduation or incorrectly diagnosed as mentally retarded or learning disabled.

Would-be reformers of the American public education system propose a voucher system as a solution to the failure of the current system. However, the cultural and cognitive flex system of education would argue that the answer to educational reform does not necessarily lie with the privatization of education, but rather with the way teaching is usually executed, with what is emphasized in learning environments, and with the way schools are organized. The objective is to eradicate factory-model schools and the one-size-fits-all mentality. When students are provided with personalized, challenging, and meaningful experiences, they are allowed to use their preferred cultural and cognitive styles and gradually learn unfamiliar styles without negative consequences. Flex development takes place and conditions are established for lifelong enthusiasm for learning and social and intellectual growth.

Cognitive and Cultural Flexibility in a Diverse and Global Society

Adaptability and flexibility are necessary to the attainment of life satisfaction and successful participation in a complex, technological, diverse, and global society. Flexibility of learning is a necessity in our new society, as is adaptability to working with people from diverse backgrounds. In a leadership research study, leaders of ethnically mixed groups, who varied in cultural and cognitive flex, were asked to make every effort to reach group consensus on solutions to group problems that were impossible to solve (the group members were instructed by the experimenter to play obstructionist roles). These leaders were observed and rated on effectiveness of effort. The findings supported the hypothesis that leaders who were more culturally and cognitively flexible were significantly more likely to use effective behaviors such as establishing group cohesiveness, soliciting the opinions of all group members, and establishing a direction for the group than the leaders who had scored lower on flexibility measures.

Encouraging flexibility through education can also reduce dropout rates and promote multicultural participation, as revealed by the findings of a long-term research study that applied the cultural and cognitive flexibility model in a Southern California school. Students in the experimental and control classrooms were matched with respect to ethnicity and family socioeconomic status. The experimental participants were exposed to the flex program from kindergarten through third grade, whereas the control group students were taught under the standard curriculum of the same school. Former participants in this study were compared 36 years later according to various outcome measures. The findings indicated that the experimental classroom participants were significantly more likely to graduate from high school, to have multicultural friendships, and to participate in activities of the different cultural groups represented in their communities of residence. They also scored higher on the reading, spelling, and math subtests of a standardized achievement test.

The challenge to improve the American system of education facing parents, educators, and social scientists is enormous. As American society and its economy become more complex, the demand for well-educated, flexible, adaptable citizens becomes more pressing. The individuality of students and teachers needs to be acknowledged and recognized, and educational environments that recognize, respect, and promote this individuality need to be developed.

COGNITIVE BEHAVIOR MODIFICATION

Cognitive behavior modification (CBM) is a blending of two conceptual models of management behavioral and cognitive theory, and as such is a powerful tool for changing trajectories of behavior in children and adults. One of the most widely researched and heavily evidenced types of therapy or intervention, CBM provides an evidence-based model for practice in public and private applications. Behavioral models of management originate with John Watson, Edward Thorndike, and B. F. Skinner and are based on learning theories of operant conditioning. Behavior is thought to be "learned" and as such can be "unlearned." All behavior serves a function for the individual, such as escape and avoidance or access to a reinforcer or reinforcement of some kind. Those reinforcers could be tangible or intangible things or conditions. Cognitive theory involves thoughts and feelings, two things that a behaviorist could not identify or measure overtly. Cognitive theorists would discuss cognitive structures and internal dialogue as the reason for behavior. This internal dialogue is also called *self-speech* or *self-talk* and is believed to be modifiable through self-instruction training, whereas a purely behavioral model would seek to change the antecedents and consequences that maintain the behavior.

Definition and Description

Cognitive behavior modification is the theory and practice that people's thinking about events, rather than the events themselves, are responsible for their actions, and that thinking can be modified and lead to behavior change. CBM involves overt behavior but also considers the verbal and internal processes that monitor and guide the more observable behavior. Interventions that are grounded in CBM include self-dialogue and thinking as component antecedents and consequences in changing behavior.

Behavioral Model: Observable and Measurable Events

Antecedent → Behavior → Consequence

Example: Jack is teased by Fisher → Jack hits Fisher → Fisher quits teasing

Jack has learned that hitting will result in escaping teasing and may be more likely to hit the next time there is an occurrence of something Jack wants to escape. A behavioral intervention would target teaching Jack to escape appropriately. This would reflect the function of the behavior (escape) while teaching a new skill to get the same need met.

Cognitive-Behavioral Model

Antecedent → Thinking/Belief System → Feeling → Behavior

Example: Jack is teased by Fisher → Jack thinks about getting teased and has a strong emotional response → The anger or frustration or embarrassment → Leads to hitting

The feelings and behavior in this model are the focus of the intervention rather than the behavior of hitting. A cognitive behavioral intervention would target the thinking and feeling or self-dialogue that occurred rather than attempt to control the consequences and antecedents.

Cognitive behavior modification is a form of intervention that emphasizes the important role of thinking in how people feel and what they do. Cognitive behavior modification involves the attribution of beliefs to people's thoughts that theoretically cause their feelings and behaviors. The benefit of this CBM model is that thinking and beliefs are conceptualized as learned. Thinking, feeling, believing (self-talk, self-narration, self-schema) as a learned behavior means people can change the way they think in order to feel or act, regardless of the situation. CBM can be thought of as a theory, a system of strategies, and a series of techniques. The theory is based on the idea that the processing of information is crucial for the survival of any person or individual.

Cognitive-behavioral therapists teach that when people's brains are healthy, it is their thinking that causes them to feel and act the way they do. Therefore, if a person is experiencing unwanted feelings and behaviors, it is important to identify the thinking that is causing the feelings or behaviors and learn how to replace this thinking with thoughts that lead to more desirable reactions.

Purpose

Theoretically, cognitive-behavioral therapy can be employed in any situation in which there is a pattern of unwanted behavior accompanied by distress and impairment. It is a recommended treatment option for a number of mental disorders, including affective (mood) disorders, personality disorders, social phobia, obsessive-compulsive disorder, eating disorders, substance abuse, anxiety or panic disorder, agoraphobia, posttraumatic stress disorder, and attention deficit/hyperactivity disorder (ADHD). Patients with sleep disorders may also find cognitive-behavioral therapy a useful treatment for insomnia.

Cognitive-behavioral therapy combines the individual goals of cognitive therapy and behavioral therapy. Pioneered by psychologists Aaron Beck and Albert Ellis in the 1960s, cognitive therapy assumes that maladaptive behaviors and disturbed mood or emotions are the result of inappropriate or irrational thinking patterns, called *automatic thoughts.* Instead of reacting to the reality of a situation, an individual reacts to his or her own distorted viewpoint of the situation. For example, a person may conclude that he or she is "worthless" simply because he or she failed an exam or didn't get a date. Cognitive therapists attempt to make their patients aware of these distorted thinking patterns, or cognitive distortions, and change them (a process termed *cognitive restructuring*).

Behavioral therapy, or behavior modification, trains individuals to replace undesirable behaviors with healthier behavioral patterns. Unlike psychodynamic therapies, it does not focus on uncovering or understanding the unconscious motivations that may be behind the maladaptive behavior. In other words, those who are strictly behavioral therapists don't try to find out why their patients behave the way they do, they just teach them to change the behavior.

Cognitive-behavioral therapy is used to mitigate maladaptive behaviors through the use of covert self-statements with the behavioral modification techniques of behavioral therapy. The therapist works with the patient to identify both the thoughts and the behaviors that are causing distress, and to change those thoughts in order to readjust the behavior. In some cases, the patient may have certain fundamental core beliefs, called *schemas*, that are flawed and require modification. For example, a patient suffering from depression may avoid social contact with others and suffer considerable emotional distress because of this isolation. When questioned, the patient reveals to his therapist that he is afraid of rejection, of what others may do or say to him. Upon further exploration with his therapist, they discover that his real fear is not rejection, but the belief that he is uninteresting and unlovable. His therapist then tests the reality of that assertion by having the patient name friends and family who love him and enjoy his company. By showing the patient that others value him, the therapist both exposes the irrationality of the patient's belief and provides him with a new model of thought to change his old behavior pattern. In this case, the person learns to think, "I am an interesting and lovable person; therefore, I should not have difficulty making new friends in social situations." If enough irrational cognitions are changed, this patient may experience considerable relief from his depression.

Interventions

Intervention in CBM works on the identification of one of two types of beliefs: rational and irrational. Several types of interventions work from this basic principle.

Cognitive restructuring is the process of replacing maladaptive thought patterns with more constructive thoughts and beliefs. Maladaptive thoughts are those considered unsuitable or counterproductive; for example, maladaptive behavior is behavior that is inappropriate to a given situation.

Verbal mediation is the process of identifying the self-talk or inner speech that will lead to goal fulfillment or task achievement. A script of self-talk that corresponds to the targeted or desired behavior is used in mental rehearsal to shape behavior.

Problem solving involves deconstructing problem scenarios and developing alternative causal explanations and inferences along with alternative solutions or behaviors. These alternatives are then mapped to

determine best choices or best options for subsequent conditions of the same problem.

Self-instruction is the process of teaching steps toward task completion. There are specific steps in self-instruction as follows:

1. *Demonstration by Model.* The teacher/therapist models behavior and says out loud what he or she is doing.

2. *Modeling With Overt Adult Guidance.* The student/client performs the task while talking to him- or herself out loud. The teacher/therapist corrects the student/client, helps with difficulties, and gives positive feedback.

3. *Modeling With Overt Self-Guidance.* The student/client performs the task while orally talking him- or herself through without guidance from the teacher/therapist.

4. *Modeling With Faded Self-Guidance.* The student/client whispers the self-guidance while performing the task.

5. *Self-Guidance.* The student/client speaks silently while performing the actions.

Tips for Implementation. Frequent practice is needed for fluency and mastery. Participants all need verbal rehearsal and opportunities for application. Start small before tackling large issues. Use visual prompts.

Benefits

CBM has been reported to have a host of benefits. Individuals report having more self-control, and some research reports its use for increasing time on task in classrooms, improved performance on intellectual tasks, decreases in impulsivity, and increases in attention. Other positive effects include an increased awareness of feelings and maladaptive belief systems, as well as an increase in self-evaluation of how behaviors related to personal behaviors.

CBM has demonstrated effectiveness for many children who benefit from modeling and rehearsing. CBM increases the attention of children after limited treatment exposures. CBM improves the processing abilities of aggressive students and increases problem-solving abilities. For students with ADHD, CBM has demonstrated effects for reducing the impulsiveness of many students by having them implement problem solving, and for students with learning disabilities,

anxiety disorders, depression, anger, and impulsivity, improved performance is expected from CBM.

Cognitive behavior modification is different from psychodynamic therapy, and they should not be confused one for the other. Psychodynamic therapy is a therapeutic approach that assumes that dysfunctional or unwanted behavior is caused by unconscious, internal conflicts and focuses on gaining insight into these motivations. CBM is a focus on the verbal behavior of an individual. It is covert but not unconscious. This verbal behavior is also conceptualized as automatic thoughts, which automatically come to mind when a particular situation occurs. Cognitive-behavioral therapy seeks to challenge automatic thoughts for their rational or irrational basis. Schemas are the fundamental core beliefs or assumptions that are part of the perceptual filter that people use to view the world. Cognitive-behavioral therapy seeks to change maladaptive schemas. Relaxation techniques are sometimes used to relieve stress. Exercise, biofeedback, hypnosis, and meditation are all effective relaxation tools. Relaxation techniques are used in cognitive-behavioral therapy to teach patients new ways of coping with stressful situations but are not a direct component of CBM.

Future research on CBM includes a need for data on the long-term effectiveness of using the procedures and the applicability for individuals with specific disabilities, such as attention deficits and emotional and behavioral disabilities across ages.

COGNITIVE DEVELOPMENT AND SCHOOL READINESS

Many of those who remain committed to Jean Piaget's cognitive developmental theory see important implications for our conceptions of readiness for formal aspects of school learning. The general principle of strong correlations between measures of cognitive development and school achievement is complemented by Piaget's proposal of a hierarchical sequence of four cognitive developmental stages: sensori-motor, pre-operational, concrete operational, and formal operational stages. In many Western school systems, the timing of the movement of children from the informal learning settings of kindergarten and preschool to the first year of formal curriculum-based learning in primary or grade school coincides with the transition from pre-operational to concrete operational modes of thinking. Furthermore, the change in curriculum demands of theoretical mathematics, language, and science learning (for example) in high schools or secondary schools often occurs as students' minds are claimed to be in transition from concrete operational to formal operational thinking. However, whereas the timing of the school transitions is remarkably age-determined, the corresponding cognitive developmental transitions are merely age-related.

Three particularly important and widely implemented pedagogical outcomes of the study of cognitive developmental theory have been the play-based nature of preschool learning experiences, the hands-on approach to mathematics learning in the grade school years, and a problem-solving approach to high school science curricula. For almost two decades, two key U.S. journals, the *Journal for Research Into Science Teaching* and *Science Education*, were dominated by reports on the relationships between high school science learning and formal operational thinking. Researchers such as Anton Lawson, Warren Wollman, and Robert Karplus were foremost among researchers of that era. Although many would observe that the Piagetian influence in science education is well past its zenith in the United States, that is not the case in the United Kingdom, and that is certainly not the case for preschool education. The remarkable success of the team of Michael Shayer in the United Kingdom in applications to high school science pedagogy, in particular, and education in general, shows the benefit of theoretically informed long-term commitment. Preservice education of early years teachers remains under the sway of the Piagetian oeuvre and the early influence of Constance Kamii has been continued by others, such as Rheta Devries and Betty Zan.

Readiness for High School Science

Shayer and part of the Concepts in Secondary Mathematics and Science team at the University of London devised a cognitive demand taxonomy directly from the Barbel Inhelder and Jean Piaget book on the development of formal thought and used it to estimate the intellectual demands of the U.K. national high school science curriculum. Their subsequent representative national survey of children's cognitive development revealed a pedagogically important mismatch between the cognitive demands of the science syllabus content and the cognitive developmental capacity of high school students in the United Kingdom to understand that material. Therein lies the conceptualization of the relationship between cognitive development and lesson content as it relates to school readiness: The cognitive demands of the formal curriculum exceed the cognitive capacity of many students who have been promoted into that new school setting on the basis of some age-determined criterion. Two alternate resolutions for this mismatch seem possible in order to address the readiness for learning issue: reduce, reorganize, or reschedule the cognitive demands of the curriculum for all/many/some learners; or promote the students on the basis of cognitive readiness for learning rather than by age. In the face of intransigence of curriculum experts, or, in the U.K. situation, the demands of university entrance exams, a third, much more radical, solution seemed appropriate to Shayer's team. They developed the *Thinking Science* intervention to maximize the development of formal operational thinking structures in middle school and junior high school students. *Really Raising Standards* reported that not only were cognitive development rates improved, but students who received the

special thought-provoking lessons later outperformed controls in science, mathematics, and language on the national public examinations used to decide access to universities. Lorna Endler found similar results for her replication of the project in Australia, which prompted a district-wide Goals 2000 implementation in Oregon in the United States. Stanbridge's research on her own radical constructivist science teaching over almost a decade revealed that understanding of core physical science concepts was constrained by the level of cognitive development of the learner; a cognitive ceiling on achievement was implied by Panizzon's research with high school, college, and university students.

Readiness for Year One

Birthday-related entrance into formal, year one learning is almost ubiquitous in Western schooling systems. Cognitive developmentally informed investigations into school performance in the early years yield three results that are quite consistent with the findings from the high school research above. The summaries provided in Bond derive from a sequence of studies in which research students measured both students' levels of cognitive development and their school achievement using either mandated or teacher-made assessments. First, cognitive development is remarkably heterogeneous for any school group selected by age or year of schooling. Second, curriculum requirements are out of the grasp of many students based on their Piagetian level of cognitive development. Finally, academic success at grade/primary school clearly is related to that development. The general findings are that academic success is apparently more dependent on cognitive development than on the age (or year level) of the child. This implies a consequently smaller role for curriculum and learning experiences in school achievement. The wide range of achievement for any age cohort is consistent with the huge variability in stage of cognitive development in any age-determined class group.

These generally consistent results prompted Maley to address directly the question of the preschool to year one transition and the roles played by cognitive development and the social/psychomotor indicators often recorded by preschool teachers. Predictably, children at the end of their preschool year found it much more difficult to provide conservation of number judgments with appropriate operational justifications

than they did to fulfill the requirements of their teachers' readiness checklist. Moreover, year one teachers were measurably less likely to judge children in the newly arrived year one cohort as "nearly ready" or "ready" for formal learning than were their preschool teachers just before the summer break. Tellingly, from the point of this encyclopedia entry, the indicators of concrete operational thinking were closely aligned to the readiness judgments of the year one teachers, suggesting a key role for considering cognitive development when assessing readiness, along with a need for preschool and year one teachers to construct a shared understanding about the "readiness" construct.

At the level of preschool education, Rheta DeVries and Betty Zan also propose important consequences for children's moral development that derive from a constructivist account of education derived from the theory and research of Piaget. They argue against more traditional approaches for the moral education of young children.

COGNITIVE VIEW OF LEARNING

Cognition refers to thinking and the mental processes humans use to solve problems, make decisions, understand new information or experiences, and learn new things. *Cognitive views of learning* focus on cognitive variables affecting learning—what goes on in people's minds before, during, and after learning. For example, when students are preparing to read a textbook chapter, they might think about what types of learning strategies they want to use to learn the important material in the chapter. They might decide to take notes and organize the material as they are reading, or to paraphrase each section as they read to see if they understood the material. Thinking about what learning strategies to use before starting to read may help students to read and learn more effectively. During the time they are reading, students can use the learning strategies they picked and check to make sure their strategies are working and that they are learning the material. After reading the text, students could think about what they did and decide if this was a good way to learn the material in this textbook. If it was, they might decide to use these methods again. If not, they may want to try something new when they read another chapter in this text. This example captures the essence of the cognitive view of learning—the most important part of learning goes on in the learner's mind. Studying these cognitive processes and fostering their development in children and adults is a major focus of educational psychology.

Cognitive views of learning have expanded both the breadth and depth of how people understand learning and the interactions among learners, teachers, and instructors; the learning environment; and learning materials. Not all students learn the same way, use the same methods, or interpret the environment identically. These individual differences or preferences for ways of thinking and learning have led educators to modify their teaching methods so that they are better able to provide support for individual students. Research on individual differences has led to the development of models of learning that focus on different types of cognitive processes and how they interact to produce meaningful learning rather than simple memorization. The focus of meaningful learning is on understanding and creating relatively long-term clusters of related knowledge and skills.

Models of how students process new information and experiences have evolved over time into complex, interactive cognitive models of learning. These models focus on goal-directed learning that involves the intentional use of cognitive, metacognitive, motivational, emotional, and self-management strategies and methods to reach learning and achievement goals. Successful learners think about and set goals for what they want to achieve, which helps them target and direct their use of learning strategies and methods. Setting and thinking about goals can also enhance motivation and commitment to learning. Using cognitive learning strategies involves building bridges between what the student already knows or has experienced and what he or she is trying to learn. For example, comparing and contrasting the political and economic causes of the Vietnam war with the Iraqi war can help students understand the Iraqi war. Thinking about what they experienced when they flew on an airplane can help students understand the physics of flight.

Metacognition refers to thinking about thinking. It is a metaprocess, that is, a process that goes along with another process to support it in some way. For example, solving a math problem involves cognition. Thinking about which cognitive processes to use to solve the math problem involves metacognition. Because educational psychologists know how critical it is to use effective cognitive strategies for learning, the importance of metacognition for learning is widely recognized. Motivation and emotion also have a significant impact on learning and have strong cognitive components. Thinking about how an individual can use something he or she is learning now or in the future can increase his or her motivation for learning. Keeping a positive attitude toward learning can also help students stay on task and not procrastinate.

The last area, self-management, involves planning, monitoring, regulating, and evaluating how one goes about learning. Students can benefit from using a systematic approach to learning. Basically, this involves setting a goal; selecting the cognitive learning strategies and other methods to use to learn the material;

implementing the methods selected; monitoring and evaluating the learning process to make sure progress is being made toward the goal; modifying or replacing strategies if they are not contributing to goal progress; and, at the end, evaluating the entire process to see if it is reasonable to try to complete a learning task like this the same way in the future or if it would make more sense to try different strategies and methods. Using a strategic approach to learning helps students build up a set of routines—sequences of thoughts and actions—that is effective for them so that they do not have to "reinvent the wheel" every time they try to learn something. For example, many people have established routines for how they read a favorite magazine and do not have to think about their goal or what learning strategies to use each time they read a new issue. In the same way, students who are being strategic should not have to think about how to read a chapter of text every time they read the same textbook, or when they are taking notes in class or completing a multiple-choice test.

Building on cognitive views of learning, educational interventions have been developed to help students succeed at all levels of formal education, industrial education and training, and everyday learning. This is a key area of research and work for many educational psychologists.

COMMUNICATION DISORDERS

The ability to communicate using speech is one of the most effortless, taken-for-granted human faculties. Its importance, however, becomes readily apparent when an individual fails to acquire the skill, loses the skill, or cannot use it effectively. Hearing and speech are inextricably connected: Development of language and speech depends on the exposure to spoken language during the early years of life. The range of speech communication disorders that arise during a lifespan are many, and they fall in the province of the field of speech-language pathology and audiology. Speech communication is the major focus of these fields. However, speech-language pathologists also give due importance to other modalities of expression—writing and signing—in their work.

Speech communication can be viewed as transmission of a message from a speaker to a listener. The linguistic encoding and transmission of a message by a speaker is a complex process; the reception and recovery of the message by a listener is an equally complex process. The field of communication sciences (speech and hearing sciences) provides empirical and theoretical underpinnings for the field of communication disorders. These fields are truly interdisciplinary in nature, drawing on wide-ranging fields in the physical, biological, and psychosocial sciences. Speech-language pathologists (SLPs) and audiologists diagnose and treat (manage) a variety of speech communication disorders in multiple settings, such as hospitals, schools, and nursing homes. To get a brief introduction to a sample of communication disorders that a certified SLP and audiologist is called upon to diagnose and treat (manage), the communication process must be considered in some detail.

Speech Production Process

Generally, three stages in the central brain processes are posited prior to production of speech. Each stage can be conceived of as a neural activation pattern that evolves and morphs at a fast pace into a pattern associated with the succeeding stage. The foregoing description suggests that the stages are organized serially, that is, processing in one stage is completed before the processing in the succeeding stage begins. However, there is evidence to suggest that processes in the stages and within each stage are part serial and part parallel. Thus, for example, fitting words in proper grammatical slots in a sentence does not occur one word at a time from beginning to the end but in parallel. This view is supported by a variety of slips of tongue data (e.g., **Intended**: *The map is in the car.* **Produced**: *The car is in the map*).

The first stage is thought processes leading to message formulation. Thought is language-neutral and, by symbolically representing thought using the vehicle of language, the message is made available to the conscious mind. This prelinguistic stage is generally conceived to be beyond the purview of communication sciences.

In the second stage, the message undergoes linguistic formulation. Linguistic formulation involves multiple processes such as selection of language to be used (if a speaker knows more than one language and the listener is equally competent in that language), the retrieval of words from the lexicon—long-term storage—to be fitted in a preselected sentence structure (syntactic frame) that specifies the linear order of parts of speech (grammatical categories) and phonological structure (i.e., how the sentence will sound).

The third stage is conceived to be motor planning of the linguistically formulated message. Motor planning is specification of timing and extent of muscle group contraction-relaxation in the peripheral organs involved in speech production. These organs, collectively referred to as the *speech production system*, compose the respiratory system, the laryngeal system, and the oro-nasal-pharyngeal system. The patterned muscular contraction-relaxations result in movement of ribs, lungs, vocal folds, velum (soft palate), jaw, tongue, and lips, all geared toward controlled expulsion of air and generation of sound using vocal folds, which in turn are shaped into a nearly concatenated series of overlapping sounds called speech. The motor plan reflects the sound- and word-specific movement requirements. Additionally, the motor plan also encodes for the effects the speaker intends the message to have on the listener. Thus, a speaker may state, persuade, seek to clarify, or seek clarification. These goals change the movement underlying a word sequence and hence the sound output. These changes are called *prosodic changes*. Prosodic changes can be illustrated by an example. A speaker may state "This book is interesting" or stress the word "This" to emphasize that this book, and not some other book, is interesting. In addition, the speaker may want to communicate enthusiasm, disgust, anger, irony, or approval. These affective components also contribute to changes in global and local acoustic features of the produced sentence. These changes are collectively referred to as *paralinguistic changes*.

A message repeated twice might not involve exactly the same motor plan. Motor plans are altered to respond to the current constraints on the speech mechanism. To take a simple example, to produce /p/ in the word "pat," the instructions to approximate the lips would differ depending on the current position of the lips. If the mouth is currently open, the muscles of the jaw as well as the lips will be involved in lip approximation. On the other hand, if the mouth is closed, the same target sound is achieved without the activity of jaw muscles. Peripheral sensory or afferent inputs inform central motor planning mechanisms about the existing constraints. In normal speech production, a rapid contextual adjustment is the rule rather than the exception. The use of different muscle groups to achieve the same acoustic/perceptual target is called *motor equivalence*. Motor equivalence underscores the principle that the brain uses variable means to achieve invariant ends.

The most important sensory signals arise from tactile (sense of touch) and proprioceptive mechanisms in the speech production system. They inform the motor planner about the constraints prior to initiation of speech. These feedback signals are supplemented with auditory feedback signals once speech begins.

Peripheral feedback is crucial during the early years of speech and language acquisition; their role in adult skilled speakers is still a matter that needs to be settled. Do skilled speakers depend on them all the time to monitor the progress of an utterance? There is ample evidence to show that they play a role in getting the production back on track if there is a sudden, unexpected perturbation to the speech production system. The relative importance of the type of feedback signal—auditory, tactile, or kinesthetic—is also an open question.

Respiratory, laryngeal, and oro-naso-pharyngeal structures have dual life-supporting functions: breathing and eating. Quiet breathing is automatic and governed by the respiratory centers in the medulla oblongata. During quiet breathing, durations of inspiration and expiration are nearly equal. While speaking, however, the duration of expiration is considerably increased in relation to the duration of inspiration. This change represents an active modification of expiratory muscle activity to generate a steady expiratory stream as a power source for speech.

The vocal folds in the larynx (commonly referred to as voice box) move to the midline to impede the expiratory breath stream. When the air pressure below

the folds exceeds air pressure above the folds in the vocal tract (pharynx, oral and nasal cavities), the folds are forcefully opened and set in a periodic to-and-fro movement, generating a voice. By changing the degree of vocal fold approximation (or degree of impediment to the flow of air) and the folds' length and tension, a speaker can generate degrees of emphasis (stress) and pitch to achieve linguistic, prosodic, and paralinguistic goals.

The voice (sound) is transmitted and modified by changing configuration of the vocal tract. The various cavities of the vocal tract act as acoustic resonators. Continuous speech involves rapid changes in vocal tract configuration, which in turn engenders rapid changes in resonating characteristics. The changes in resonating characteristics, in large measure, underlie the distinction between serially organized speech sounds produced during continuous speech. Changes in vocal tract configuration are achieved by the movement of lips, jaw, tongue, and velum.

Language Processing and the Brain

It has been known that the left hemisphere of the brain is dominant for language processing in most individuals ever since Paul Broca's description of a patient with a lesion in the left inferior frontal cortex region of the brain. The patient had effortful speech with relative preservation of comprehension skills. The clinical data from patients with lesions in the left hemisphere show that there is a degree of modularity—the frontal lesions generally affecting flow of speech while preserving comprehension, whereas posterior lesions in the parietal lobe affect comprehension skills while preserving flow of speech. There have been considerable attempts to relate symptoms with sites of lesions, with some degree of success. However, correlating symptoms with sites does not reveal how a brain functions in a healthy individual when engaged in various language tasks. The glimpses of complexity of neural activity when the brain is engaged in such simple language processing tasks as naming pictures and matching an appropriate verb with a stimulus noun are being highlighted by modern neuroimaging techniques such as functional magnetic resonance imaging, positron emission tomography, and magneto-encephalography. Such techniques reveal that there are multiple regions of activations within the left language hemisphere and the nondominant right hemisphere.

Disorders arising during linguistic formulation are collectively termed *aphasia* or *dysphasia.* Thus, a patient may have a problem in retrieving lexical items or words (anomia) from the lexicon, a problem with syntactic processing (syntactic aphasia), or a problem in sequencing the phonemes (apraxia) that constitute individual words. Aphasia typically results from cerebrovascular accidents such as hemorrhage, embolism, and ischemia in the left hemisphere. Children may exhibit language formulation issues even without brain lesions.

Hearing and Speech Perception

The process of recovery of encoded messages starts in the peripheral hearing mechanism (ear). The ear has three distinct parts: external, middle, and inner. The acoustic energy in the ear canal is converted into mechanical energy of the intricate motion of the ear drum and the three middle ear ossicles (bones). This motion in turn produces vibration of fluid in the inner ear. The motion of the inner ear fluid results in the motion of the basilar membrane. The end organs (hair cells) of the auditory nerve are located on the basilar membrane. Different regions of the basilar membrane are responsive (resonate) to different frequencies. Hence, the inner ear activity results in spectral (frequency by intensity) analysis of speech in terms of patterned excitation in the auditory nerve. The patterned excitation reaches the primary auditory cortex in the temporal lobe of the brain where sound is sensed. The secondary auditory cortex surrounding the primary auditory cortex is involved in putting the analyzed signal back (fusion) to recover the literal message and then the intended message.

The aforementioned thumbnail sketch of the hearing process provides a strictly serial view of hearing and speech perception. However, speech perception, defined as recovery of the sequence of phonemes constituting an utterance, is anything but serial. At any given point in time, a listener is not only analyzing the speech but also bringing to bear on the analysis contextual and knowledge constraints to arrive at a decision regarding sound and word identity. Thus, speech perception involves both bottom-up processes (acoustic input analysis) and top-down processes (contextual and knowledge constraint inputs to the analysis). There is considerable evidence supporting the idea that as a listener begins processing a spoken

word, the initial input (beginning of the word) activates a cohort of candidate words with that beginning. But as more and more of the spoken word unfolds, all the words are rejected (deactivated) in favor of the one the speaker intended. This is the idea behind Internet search engines with a search history—as an individual types a few beginning letters of a word, the system presents multiple candidate words beginning with the letter sequence. As the individual types more letters, more and more candidate words are rejected in favor of one the individual had used previously.

Communication Disorders in Educational Settings

Hearing Loss, Speech, and Language Development

Communication disorders can arise at any level of the communication process outlined above. An additional complication arises when communication disorders in educational settings are considered. Preschool and elementary school years are the years when children grow at a rapid pace physically, cognitively, and linguistically. There is a strong reason to believe that human children are biologically equipped to extract language from speech to which they are exposed. In essence, growing children implicitly acquire a system of rules (grammar) that will enable them, in Noam Chomsky's words, to understand and produce sentences that they have never heard before or produced before. However, there seems to be a critical period—roughly between birth and preadolescent years, and particularly between birth and 5 years—in which a child needs to be exposed to a language. A child's growth in other departments—cognitive, affective, and neuromuscular—must go hand in hand for a child to be an age-appropriate communicator.

The acquisition of language may be delayed in an otherwise normal child because of frequent middle-ear infections that result in temporary or permanent loss of hearing. The effect of frequent infections depends on whether the condition is unilateral or bilateral. Unilateral conditions typically do not affect language development; bilateral conditions do. The degree of hearing loss will have a direct impact on the phonological development—mastery of language-specific sound distinctions and word-specific changes that signify tense, number, and so on. A serious deficit in the middle-ear transmission function can result

in a 30- to 50-decibel (dB) sound pressure level (SPL) loss in the speech signal strength. Normal face-to-face conversation is typically around 60dB SPL. In this condition, the child is barely hearing speech and is missing most of the consonants, which are shorter and less intense than vowels. These phonological problems can be remediated effectively by addressing the hearing problem—using a hearing aid to amplify sounds—and with speech therapy that creates awareness of sound distinctions and direct speech therapy.

The extreme case is children who do not hear at all due to diseases—congenital or acquired—that affect the inner-ear processing. There are degrees of sensorineural hearing losses, and accordingly, one can expect degrees of language delays and impairment. A severe inner-ear impairment is generally recognized by parents or a caregiver; less severe conditions may receive delayed identification. In these conditions, early diagnosis has a direct impact on the effectiveness of rehabilitative procedures. Teachers and caregivers must seek professional help if they suspect hearing loss. An ear, nose, and throat specialist or an audiologist is the most appropriate person to contact. Early identification is so critical for the development of speech and language that there is a need for infant hearing screening programs.

Specific Language Impairment

Specific language impairment (SLI) is a condition in which children are normal in all respects and have adequate exposure and opportunity for learning a language but still fall significantly behind their peers. The prevalence of SLI in the general population is around 7%. An SLI child scores normal or above normal on nonverbal intelligence tests and does not have hearing loss, brain damage, or any other physical abnormality that can explain significantly low performance on language tests. A few recover, but many continue to suffer. SLI is significantly correlated with reading impairment.

Most English-speaking SLI individuals exhibit a deficit in using bound morphemes that indicate past tense (walk-walk*ed*), more than one (book-book*s*), and done by someone (climb-climb*s*). Some investigators have suggested that an SLI child has difficulty processing brief, rapidly unfolding sounds as an explanation for language impairment. This explanation suggests that, at its roots, it is a perceptual problem.

Several lines of evidence suggest a genetic basis for the disorder: More males than females have SLI, there is aggregation of SLI in families at a rate beyond the general population rate, and there is greater concordance (i.e., both suffer) among identical twins rather than fraternal twins.

There has been an in-depth investigation of a family (KE family) that had significant aggregation of individuals with SLI. The aggregation pattern in a three-generation pedigree indicates a strong autosomal dominance pattern. The genes responsible for this particular family's disorders have been mapped to a particular area on chromosome 7, and genetic analysis of an unrelated patient who exhibited similar language problems revealed a mutation in this same region. Although further studies are necessary, it may be that this mutation leads to a lack of a particular protein that affects the development of neural structures important for speech and language, the way similar proteins have been shown to influence neuronal development in other organisms. Subsequent study using neuroimaging techniques confirmed anatomical abnormalities in certain localized regions of the brain. The imaging study involved comparisons of brain anatomy of impaired and unimpaired members of the family. The overall genetic pattern exhibited by the KE family, especially with the discovery of the gene deletion, strongly suggests that a gene, or a small set of genes, has a major impact on language development.

Current studies are attempting to classify SLI patients into distinct subgroups based on the details of their impairment so that testing can determine more precisely the causes of the impairment.

Fluency Disorders

There are a host of disorders that affect the smooth flow of speech during early childhood. The most notable among them is developmental stuttering (DS). DS is a perplexing problem generally considered to be triggered in postlinguistic formulation stages.

Developmental stuttering, as the name suggests, manifests itself during the early years of rapid physical, cognitive, and language development. It is characterized by involuntary intermittent disruptions that take the form of fragmentation and repetitions of the beginning of words, prolongation of the initial sound of the word, or inappropriate silence or blocks. The onset is typically gradual and usually occurs when children start putting words together in sentences. The lifetime incidence of the disorder is estimated to be 5%, with a 1% prevalence rate in the population. Because the incidence of stuttering decreases precipitously from 2 to 10 years, the disparity in lifetime incidence and prevalence suggests that many children (around 80%) recover spontaneously, and a few continue to stutter into adolescence and adulthood.

The current understanding of the disorder is that it is etiologically complex, that is, both nature (genetics) and nurture (environment) play a role. The arguments in favor of a genetic basis are that it is more prevalent in boys than girls, the prevalence of stuttering in families of stutterers is significantly more than in the general population, and the concordance for stuttering among identical twins is very high compared to fraternal twins. Recent studies have shown that an autosomal dominance model, influenced by the gender of the affected individual and the affection status of the parents, is the best fit for the aggregation pattern in families. Recent neuroimaging studies have shown significant anatomical and functional differences between the brains of adult stutterers and normal speakers. The studies are still preliminary.

For a long time, stuttering was considered to be caused by anxiety, or it was considered to be something a person could overcome if only he or she tried. As a disorder, it was imitated, with negative consequences for individuals who were being imitated. The current understanding is that at its inception, it is purely a speech motor problem, and that anxiety as a factor starts having an impact on the basic problem once the disorder develops. Many researchers are focused on finding how children who spontaneously recover differ from those who do not.

Stuttering in school-age children is a big concern. The effect of this disorder on self-concept, coupled with generally negative reactions from others in the child's immediate environment, alters the child's psychosocial life. Later, it may compel him or her to limit his or her choices in terms of vocation and avocation. It is essential that teachers seek an SLP's help, and the child should be helped in the context of a team involving an SLP, teacher, and parents.

Dysarthrias

There is a large group of disorders that results from neuromuscular impairment that may affect the speed,

range, direction, strength, and timing of movements. These are due to either congenital or acquired lesions of the central nervous system. The speech symptoms can be mild or severe depending on the site and extent of the lesion. Children with dysarthrias exhibit imprecise articulation (sound production), an inability to control voice parameters such as loudness and pitch, and mis-timed speech movements. Dysarthrias occur independent of language processing disorders. Because the degree of impairment varies considerably, a thorough speech mechanism evaluation is a must to identify the problem and define the subtype of dysarthria before intervention can be planned.

Professional Training

This entry has highlighted a few communication disorders from a vast list. The field is enormous, and each disorder has an area of specialization. Diagnosis and treatment of communication disorders requires extensive training (a 4-year undergraduate program with communication sciences and disorders as a major) and a 2-year master's program followed by a year of clinical externship. Speech and language pathologists and audiologists must be certified by the American Speech-Language and Hearing Association before beginning to practice.

COMPETITION

Competition constitutes a primary facet of life, as individuals within any species strive to satisfy their needs for survival, reproduction, and successful rearing of offspring. For humans, social competition between genetically unrelated individuals of similar age is particularly salient in cultures with formal schooling and public institutions where individuals cooperate apart from families. Drawing on the child development and animal behavior literatures, this entry discusses the influences of biology, sex, culture, social structure, and age on competition between unrelated peers.

Biological substrates of competitive behavior in humans that have been identified include testosterone, cortisol, and alpha-amlyase. For example, in human males, testosterone increases in response to a competitive challenge. Winners' testosterone levels increase, whereas losers' levels decrease. Higher testosterone levels then promote positive expectations of future success.

Biological sex as well as gender identity, whether one feels male or female, relate systematically to competitive behavior. Most peer competition occurs between individuals of the same sex who compete for the same goals. Cross-culturally, beginning in the first years of life, females utilize more polite speech and nonverbal communication, such as smiling and behaving modestly, which serve to diminish retaliatory responses from potential competitors. In contrast, males more frequently exhibit behavior that invites retaliation, such as physically provocative behavior and verbal attempts to

dominate others through boasts, commands, threats, name-calling, and derisive jokes.

By middle childhood, males display more interference competition in which one individual must overtly prevent another individual from obtaining a desired outcome. In contrast, females find interference competition aversive and prefer to compete through more indirect or subtle means. Improving personal performance without reference to others; denigrating an absent competitor's reputation; or employing discreet nonverbal signals of competition, such as negative facial expressions, constitute female forms of competing. By middle childhood and increasingly in adolescence and adulthood, in their interests and leisure activities, males are more likely than females to engage in overt interference competition, frequently in the form of playing or observing competitive sports, often between unfamiliar players. In contrast, females derive more pleasure and relaxation from engaging in conversations with friends and relatives about comparisons of familiar individuals' levels of performance.

Results fit squarely within an evolutionary framework in which female mammals, who bear greater responsibility than males for their offsprings' survival, must avoid physical harm and maintain loyal social contacts in order to enhance their reproductive success. Those females who engage in competitive behavior risk retaliation which could endanger nearby offspring as well as their own ability to produce future offspring. By contrast, males, who vary more than females in reproductive success, benefit more from direct competition for mating opportunities. A male who continually attempts to outperform his male peers will hold a reproductive advantage and sire more offspring.

Local cultural norms also exert a powerful influence on absolute levels of competitiveness. Although few differences exist in early childhood, by middle childhood, children from differing countries and from varying cultural backgrounds within the same country differ in degree and form of competitive behavior. These same differences apply to cooperative behavior, and willingness to compete and cooperate frequently correlate positively, not negatively. Although scarcity of resources increases competition, when resources are plentiful but easily monopolized, this also enhances competitiveness.

Social structure also affects competitiveness. Mammalian species differ in the forms of social structures they create, such as large groups, smaller cliques, pairs, or solitary formations. Groups clearly enhance competitive behavior not only because the proportion of resources per individual declines, but also because the intensity of conflicts between individuals within a group can be regulated by third-party mediators, allies, the presence of alternate partners, and loyalty to the larger group. By contrast, conflicts between two individuals are marked by higher intensity, greater probability of harm, and enhanced likelihood of disintegration of the relationship.

Generally, human males more than females interact in larger groups, whereas females prefer one-on-one relationships. For both sexes, higher levels of competition occur in groups and lower levels between individuals. Males become engaged in intergroup competition, which intensifies as the number of individuals in each group increases. Groups likely accentuate males' competitiveness, whereas females' preference for one-on-one relationships diminish it.

Development also influences competitive behavior as children become more explicitly conscious of their own interests and better able to assimilate local cultural norms dictating levels and domains of competitiveness. Beginning in early childhood, implicit dominance hierarchies become established based on individual differences in physical prowess and social skills. Dominance is defined as access to resources, territory, and power over others. By middle childhood, skills that facilitate dominance expand to incorporate achievements in diverse domains unique to humans, such as intellectual, musical, artistic, or athletic performance. Individuals also become increasingly conscious of their relative positions within the hierarchy.

In adolescence, competition heightens as individuals begin to compete for reproductively attractive mates. Males compete with other males for physical and symbolic status, which attracts females, because high status can be converted into resources to support females and children. Females compete with other females on physical attractiveness and sociability, which attract potential stable marital partners. Coalitions form that permit individuals to increase jointly their positions in the hierarchy.

An established dominance hierarchy reduces overall competition within the social group and confines competition to individuals close in status. High- versus low-status positions in a hierarchy provide individuals with varying expectations and levels of confidence regarding success in achieving personal goals. Varying the social and physical environment modifies relative dominance position and concomitant

cognitive expectations, levels of confidence, and biological substrates.

CONDUCT DISORDERS

Conduct disorders are characterized as the more severe, chronic, and pervasive forms of behavioral problems. They include a range of inappropriate, destructive, and sometimes malicious actions that constitute psychopathology. There are several clinically diagnosed mental health syndromes among conduct disorders. These are based on the constellation of maladaptive personality traits exhibited. This chapter will review the more common forms: oppositional defiant disorder, conduct disorder, and antisocial personality disorder. In addition, an overview of risk factors and intervention methods will be discussed.

Conduct disorders have the potential to significantly diminish the quality of life and long-term achievement for individuals with these behaviors. In addition, there are substantial emotional and financial costs to educators, families, and communities resulting from aggressive and destructive acts. Fortunately, a variety of interventions are available that can improve prognosis, especially when applied early, before behaviors become habitual. A number of contributing risk factors have been identified; however, much research is still needed to better understand causal agents. Multifaceted intervention plans that target a variety of risk factors are noted to be

most successful. Additional research on treatment efficacy is also needed.

Understanding and Identifying Conduct Disorders

An understanding of conduct disorders is important to researchers, educators, and policymakers in several ways. Researchers require knowledge of conduct disorders in order to investigate diagnostic measures and treatment efficacies that improve educational outcomes for these students. Teachers need to understand classroom behavioral management strategies for conduct disorders to assist students with their academic achievement. School administrators must also understand behavior needs to ensure appropriate teacher training, empirically based service models, and systemic structures that support positive learning environments. Policymakers in government agencies and business provide a crucial role in designing curriculum materials, establishing regulations, and providing infrastructure for school systems. Therefore, policymakers also require an understanding of risk factors and treatments for students with conduct disorders.

Formulating decisions regarding the identification or treatment of maladaptive behavior requires appropriate expertise. The clinical skills of diagnosis can appear deceptively succinct, even simplistic, if symptoms are treated as a checklist of manifest items. However, diagnosis is a multifaceted and complex process, requiring substantial professional training. Although the clinician is provided a list of symptoms to identify, this information must be juxtaposed with a broader and more sophisticated understanding of normal development. Understanding the normal developmental trajectory of behavioral stages provides a good comparison benchmark for identifying abnormal behaviors. As they mature, typically developing children follow a predictable sequence when acquiring skills for self-regulation of their emotions and actions, stronger impulse inhibition, and self-awareness. A professional mental health provider will know the ages at which children and youth typically exhibit behaviors, even negative ones such as biting or rebellion. The same behaviors may be considered maladaptive for one child and not another based on age-appropriateness. For example, a 2-year-old child who threatens another child on the playground to secure a toy is viewed differently from an adolescent exhibiting the same behavior. Frequency

and chronicity of behaviors also are hallmarks. Criteria for conduct disorders will often require a specific number of incidents of a particular type over a period of time for diagnosis.

A number of additional issues warrant consideration in understanding the function of behaviors and conduct disorders. Clinicians must establish the level of impairment resulting from the conduct disorder. This can range from someone who is in imminent danger of harming others to no current impairment. The impairment range will help determine the level of services required for the individual, and often the Global Assessment of Functioning Scale codes are used to document this. Consideration must also be given for possible comorbid disorders and differentiating between disorders with similar features.

Knowledge of the dominant culture of the individual also may provide contextual information for behaviors that provides additional insight. For recent immigrants, societal norms and expectations may be considerably different, especially for persons escaping war or violent circumstances. A history of aggression only for self-defense would not constitute a conduct disorder. Even within the U.S. mainstream culture, there are urban settings where gang activity in neighborhoods can result in different adaptive behavioral expectations. For persons subject to these circumstances, a behavioral bravado or highly assertive stance may have adaptive value as it can lessen vulnerability to victimization.

A number of interpersonal situations also can create temporary states of inappropriate behaviors that are not pathological. Adults and children who experience multiple life stressors such as divorce, death, or trauma can exhibit negative behavioral changes. These can manifest as irritability, agitation, anger, or negative moods similar to conduct disorder features. However, negative behaviors usually subside quickly. Because of the sudden onset and temporary nature, these symptoms may be more consistent with adjustment disorders rather than conduct disorders. Some medication side effects can also mimic behavioral symptoms.

Oppositional Defiant Disorder

The *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision) *(DSM–IV–TR)*, published by the American Psychiatric Association, provides the symptom criteria professionals use for mental health diagnoses. Oppositional defiant disorder

(ODD) presents as a pattern of antagonistic and defiant behaviors. Youth may exhibit a variety of angry, argumentative, and vengeful behaviors. Although symptoms can be verbally aggressive and hurtful to others, ODD is not characterized by physical violence or criminal acts. Persons with ODD often lack self-evaluative insight or acceptance of responsibility and will blame others for their own inappropriate behaviors.

Conduct Disorder

The *DSM–IV–TR* diagnosis of conduct disorder (CD) differs from ODD in that behaviors violate the rights of others and generally accepted rules. Behaviors may include physical aggression or criminal acts (e.g., burglary, vandalism, rape, arson). The perpetrators can be cunning, purposeful, and deceptive in their attempts to manipulate others. When considering long-term outcomes, youth who first exhibit CD in adolescence, rather than early childhood, have a better prognosis.

Antisocial Personality Disorder

Based on criteria in the *DSM–IV–TR*, if a pattern of chronic disregard for the rights of others and compliance with the law persists at age 18, a diagnosis of antisocial personality disorder (APD) may be appropriate. The diagnosis requires CD symptomology since age 15. Behavioral features of this diagnosis include lacking empathy or guilt when harming others, manipulative interactions with others, gross irresponsibility, and criminal activity.

Risk Factors and Potential Causal Pathways

Within the literature, a number of potential risk factors for conduct disorders have been identified. They are thought to represent an interaction of multiple factors, including vulnerability, predispositions, environmental elements, and poor personal choices, that increase the risk for severe behavior problems. These include dysfunctional communication patterns, negative familial behavioral patterns, difficult temperaments, and poor emotional self-regulation. Additional factors include poverty, deviant peer associations, lower intelligence (especially verbal), presence of multiple sociocultural stressors, and comorbidity for other mental health diagnoses.

Emotional Self-Regulation

Persons with conduct disorders often engage in high-risk behaviors without consideration for consequences or the effects on others. They can be highly reactive to emotional situations or perceived injustices. They may also report impulsive actions that happen with little premeditation. Based on these behavioral patterns, some researchers suggest that conduct disorders may be the result of poor emotional self-regulation. As children mature, they typically learn to self-monitor their own feelings, inhibit first responses, and select reactions. However, youth with conduct disorders do not display these qualities. Therefore, emotional self-control is hypothesized to be either delayed or poorly developed. In addition, a significant number of persons with conduct disorders are also diagnosed with attention deficit hyperactivity disorder (ADHD). Diagnostic features can include notable impulsivity and hyperactivity as found in ADHD combined type.

Dysfunctional Communication

There is evidence through the work of researchers such as George Patterson that dysfunctional communication patterns may contribute to some behaviors in conduct disorders. Parents who exhibit an authoritarian discipline style that is coercive in nature can escalate hostility. The cycle can be perpetuated if parents respond to or make demands in a threatening manner, the child then becomes defiant, and the parent in turn raises the level of threat or anger in the commands. This process serves to increase the potential for physical altercations as well as teach coercive interaction patterns. Other researchers, including Kenneth Dodge, have identified the propensity of students with conduct disorders to misinterpret social cues that are ambiguous. These cognitive distortions can lead to inappropriate hostile interpretations of interactions with others.

Negative Familial Behavior Patterns

As noted with many other mental health diagnoses, conduct disorders are more frequent when there is a family history of similar disorders. This suggests possible biological vulnerabilities as well as a number of social learning and environmental hypotheses. Parents who also have a history of conduct disorders or are experiencing other mental health issues (e.g., depression, schizophrenia) are likely to model behaviors that reinforce negative interaction patterns. There is evidence that mothers with severe depression may not form critical early attachments with their children. In the case of parents with APD, their daily life skills can be significantly diminished. This can result in a lack of basic parenting skills that can lead to sickness, neglect, or abuse of their children. The marital relationship and financial stability are often jeopardized because parents' irresponsible and callous actions create a less stable home environment for children. It is also likely parents with APD will have a history of prosecution and perhaps incarceration that further diminishes home stability for the child.

Temperament

Temperament traits are described as relatively stable personality characteristics that influence behaviors in a predictable manner. Early theory by Carl Jung explained temperament in terms of dichotomies such as the widely acknowledge premise of extroversion and introversion. He described two preferences for learning new information, sensing with an emphasis on facts and intuition with an emphasis on concepts. Jung also noted that when his patients had a strong preference for one temperament dimension, the opposing dimension could be underdeveloped. He noted that the pathology of his psychiatric patients was often expressed in ways consistent with their temperament. For example, extroverted patients were more likely to act out or show aggression.

In studies of students with ODD and CD by Diana Joyce and Thomas Oakland, preferences have been noted for extroversion, sensing, and thinking functions. Of particular note, the students with ODD were significantly more likely than the general population or students with CD to prefer new information presented in sensing styles. This includes explicit, direct instruction presented in sequential steps that utilize concrete, applied examples and detailed facts. These characteristics may explain the propensity of children with ODD to argue about rules and not generalizing behavioral expectations across circumstances.

In their work with very young children using a physiological-based temperament model, Alexander Thomas and Stella Chess described the concept of goodness of fit. This concept postulates that when parent and child temperament styles are dramatically different, there can be less understanding and tolerance for the child's behaviors. This lack of compatible

behavioral patterns has the potential to increase conflict. Their research found that children with difficult or irritable temperaments had poorer long-term outcomes.

Educational Institution Services

Public schools from kindergarten through twelfth grade provide a wide range of general and special education services, programs, and accommodations for children with special needs. Historically, referrals for these types of services have been made by teachers, although parents may also request evaluations. Services were primarily accessed following an evaluation and classification within the exceptional student education (ESE) system. If the student qualified, conduct disorders were often served under an Emotional Disturbance classification. Students could receive services ranging from in-class consultation to small group pull-out sessions or self-contained classrooms. In severe cases, students may be served through inpatient hospital or residential treatment programs.

Based on U.S. Department of Education statistics for 2002, the Emotionally Disturbed category serves the fourth largest number of special needs students. The criteria for ESE categories are established in the Individuals with Disabilities Education Act of 2004 and do not require specific mental health diagnoses. State departments of education also provide more narrow statutes that describe specific evaluation components. If schools are compliant with federal mandates, additional funding is provided for these services.

More recently, the provision of services within school systems has changed to include a response-to-intervention (RtI) model. This model is based on several premises. First, an emphasis on prevention and early intervention is required. Second, in-class and small group services may be accessed prior to a full evaluation or placement as Emotionally Disturbed. The goal is to address student difficulties before they become chronic or more complex. Third, each level of student service requires monitoring and review of outcome data to determine the efficacy of the intervention.

The concept of RtI is still evolving, and predominant models conceptualize three or four tiers. The first tier, as applied to behavioral disorders, includes school-wide screening for behavioral or socioemotional risk factors. This is a procedure that has not been commonly practiced in the past and may identify student needs earlier as well as some students who were not noticed by teachers in the past. The second tier is often in-class or small group intervention with an emphasis on collecting data to demonstrate the effectiveness of the remediation strategies. If significant improvement in behaviors is not noted, the final tier involves a more comprehensive psychoeducational evaluation. Based on results, school personnel may advocate more intensive, frequent, and multimodal services. With the advent of RtI, a new set of skills that includes single-subject design, treatment protocol studies, and systemic personnel curriculum training will be required of educators.

Intervention Strategies

Numerous negative outcomes have been associated with conduct disorders. These include considerable financial costs to schools and communities as well as emotional distress for individuals. Students with conduct disorders receiving services for Emotional Disturbance require additional funding support and school personnel resources. They experience more discipline referrals that consume the time of behavioral deans, in-school suspension personnel, other support personnel, and expulsion proceedings. In some cases, considerable additional cost is incurred to contract with outside agencies for specialized services such as counseling therapy. Data indicate higher school failure, higher dropout rates, lower incomes, and more frequent incarceration. These factors bear substantial emotional and mental health cost for individuals with conduct disorders who do not meet their full academic potential. In lieu of both the personal and systemic costs, early intervention is crucial.

When considering interventions, it is important to note that the incidence of conduct disorders is higher for males than females, especially early childhood onset. This is an important distinction because early onset of conduct disorders is associated with poorer outcomes. There also are gender differences in symptoms, suggesting that differing interventions may be required. Girls have greater risk for prostitution, alcohol or drug use, skipping school, lying, and running away from home. Boys have greater risk for physical altercations, theft, and destruction of property. Acquiring thorough background and evaluation data for individuals can provide considerable guidance for specific needs when selecting interventions.

Socioemotional Evaluation

The initial step toward evaluation may result from school-wide screenings for risk factors or teacher/parent

recommendations. Teacher and parent clinical interviews are conducted to determine the areas of concern. The goals of interviews include documenting medical and educational history, gathering pertinent familial history, recording a temporal sequence of prior events, establishing age of symptom onset, and noting any extenuating circumstances. Topics are guided by the clinician and may include issues of family dynamics, peer relationships, and juvenile delinquency incidents. Prior remediation strategies used for the student and their effectiveness, as well as student strengths, are solicited to inform later intervention choices. Consideration for student strengths and interests is particularly important to fostering early successes during intervention and identifying reinforcers for behavioral modification plans. Behaviors of concern are noted in clear, objective descriptions that can be measured later.

With objective and measurable descriptions of target behaviors, direct observations can be conducted. These data have many formats, including anecdotal records that indicate antecedents and consequences, as well as frequency and duration measures. Data collected prior to intervention can serve as the baseline for treatment. They may also be analyzed to indicate patterns, such as time of day, particular tasks that prompt behaviors, or specific locations in which behaviors escalate.

Several nationally recognized omnibus rating scales are available that sample a broad range of externalizing and maladaptive behaviors. These scales may be administered to teachers, parents, and the students themselves. They provide a cross-informant analysis to identify patterns of concern. Norm-referenced T scores are calculated to indicate average, at-risk, and clinically significant range behaviors in comparison to other individuals their own age. Numerous single-construct measures are also available to explore more narrow issues (e.g., opposition) with a greater number of items and specificity.

Because conduct disorders are often associated with poor adaptive skills, particularly interpersonal relations and communication, an adaptive measure may be used. Adaptive rating scales measure social, conceptual, and everyday practical skills. In addition, there are temperament, social skills, study habit, and self-concept measures that will help provide a more comprehensive review of the student's skills. Intelligence and academic measures can identify general cognitive abilities and specific academic skills. Addressing academic needs is particularly important to a multimodal intervention design because learning has an impact on task frustration, school motivation, and long-term achievement.

Systemic Interventions for Conduct Disorders

Systemic interventions can be applied when school-wide changes in behavior are needed because problems affect many students. These procedures may be most useful when there are frequent behavioral discipline incidents within a particular school or several students are engaging in behaviors that victimize others routinely, such as bullying.

Positive Behavioral Support

Positive behavioral support is a systematic intervention that focuses on ensuring that the school environment provides a positive, nurturing climate that reinforces appropriate actions. The focus is on lowering behavioral referrals and preventing discipline incidents rather than reacting after misconduct has occurred. It is recommended that strategies be implemented school-wide across classrooms and grades. This provides a clear, consistent structure where students know the expectations for behaviors. Desired behaviors are stated in prosocial terms (e.g., personal responsibility, sharing, respect, cooperation) and emphasize the well-being of all students, as well as school pride. Some programs include public reinforcement or rewards that provide recognition for appropriate behaviors (e.g., good citizen prizes). Expectations for positive behaviors are clearly communicated throughout the school. This can be accomplished through posters, banners, school slogans, and even morning announcement slogans. Because these strategies are comprehensive, the participation of administrators and teachers is crucial. This can require some initial training to ensure that all school personnel understand and reinforce the concepts.

Environmental Structure Changes

Another systemic intervention within schools to control disorderly conduct is the strategy of incidence mapping with structural modification. The goal is to prevent or lower disruptive incidents by limiting the opportunities for covert actions. A review of the campus grounds is conducted with an analysis of all the

schools behavioral discipline referrals. The objective is to identify patterns of incidences related to environmental routines or structures. Examples include frequent incidents in isolated areas, unsupervised areas, or areas that are not well lit (e.g., bullying in bathrooms). Easy preventive measures to lower these incidents include better lighting, ensuring that adult supervision is nearby, and sometimes changing structures. Incidents may also cluster around certain activities, times of day, or locations that are overcrowded. Examples include busy cafeterias, too many student lines passing simultaneously in crowded halls, or rowdiness during bus loading. Easy remedies include changing travel routes, staggering access to areas, or increased supervision.

Social Learning Curriculum

A number of published curriculum packages are available to schools that incorporate prosocial themes. These may be integrated into academic curricula to reinforce concepts of altruism, self-control for emotions, good problem-solving skills, and even social skills. They may also be introduced periodically, often through school counselors, as special sessions to remind students of appropriate behaviors and reasons for those choices.

Small Group and Individual Interventions for Conduct Disorders

A number of small group and individual interventions have demonstrated positive effects for diminishing conduct problems. Small group interventions are often limited to a few weeks and target a specific common need that several students may have. Examples include social skills training, anger management, conflict resolution, grief counseling, or test anxiety/frustration. A number of small group curricula are available, and they generally have the following components: opening exercises for rapport, identification of feelings, teaching of three to five new coping strategies, practice to generalize the new skill, and a follow-up or booster session.

Behavioral Modification

Operant conditioning principles are the basis for behavioral modification. This technique typically targets specific, individual behavioral goals. Reinforcers

and punishment can be used to promote desired behaviors or lower inappropriate behaviors. Reinforcers may include verbal praise, tangible prizes, token economies, and the opportunity to engage in preferred tasks. Punishments may include time-out and overcorrection techniques. Once specific behaviors are targeted, baseline data on the frequency of the behavior are collected. As the behavioral modification plan is applied and appropriate behaviors are reinforced, data are collected to determine the effectiveness of the intervention.

Cognitive Behavioral Therapy

Cognitive behavioral therapy is based on the premise that distorted or dysfunctional thinking patterns can result in maladaptive behaviors. Therefore, the target of intervention is to identify and change existing thinking patterns to new, more adaptive patterns. Methods include teaching relaxation training, gradual exposure to a feared situation, learning replacement thoughts, and biofeedback to control physiological reactions. Applications to conduct disorders include teaching students to recognize the precursors to explosive anger, providing self-calming strategies to lower arousal states, and modeling alternative problem-solving solutions.

Parent Training

Parent training can be an effective intervention for conduct disorders. In some cases, school personnel and parents may collaborate to provide a consistent behavioral modification plan across the two settings. Parenting programs often stress noticing the positive behaviors of children, using reinforcement to shape behaviors, and providing clear expectations for behavior. Authors such as Russell Barkley have designed training modules that teach parents of defiant children how to implement successful behavioral strategies at home. Techniques include the use of a token economy and time-out methods.

Psychopharmacology

There are a number of medications used to treat behavioral symptoms for some persons with conduct disorders. Stimulants may be prescribed when conduct problems are related to ADHD, impulsiveness, or hyperactivity. These include Adderall, Concerta, Cylert,

Dexedrine, and Ritalin. A class of medications called selective serotonin reuptake inhibitors (SSRIs) is often used to treat depression and panic syndromes. Paxil, Prozac, and Zoloft are common SSRIs. Wellbutrin, Effexor, Risperdal, and Depakote may lessen behavioral symptoms related to anxiety, severe mood changes, and bipolar disorder. The use of medications for children is controversial because limited research studies demonstrating treatment efficacy are available for some age groups. In addition, there are few studies on the possible long-term side effects of drug usage for children.

CONFIDENCE INTERVAL

Quantitative research in educational psychology benefits from using sample data to describe the wider population of interest. A confidence interval (CI) is a statistical approach that uses sample data to determine a range of values on a particular statistic (e.g., mean) for a sample from the population. In theory, a confidence interval is based on an infinite number of random samples from the population. For each of these random samples, a statistic of interest, such as the mean, could be calculated. Of course, it is highly unlikely that each of these means will be equal to one another, and even more unlikely that any or all of the means will equal the population mean. Thus, it is generally safe to assume that error will be present when estimating a population parameter with a statistic based on a random sample. Comparing the CI to the sample mean provides the researcher a means for determining the magnitude of error.

A CI consists of two numbers, often referred to as lower and upper bounds, between which the value of a population parameter is expected to fall. For instance, the CI for a population mean is typically reported in the following format:

$$CI_{PI} = LowerBound < \mu < UpperBound,$$

where CI_{PI} indicates the probability factor for the respective confidence interval, and μ represents the population mean. In general, probability factors of 90, 95, and 99 are used to construct CIs. For interpretation purposes, these probability factors are converted to percentages. For instance, using a probability factor of 95 results in a 95% CI, which indicates that the researcher can be 95% confident that the population mean falls within the lower and upper bounds of the interval. As another example, consider a 95% CI for mean scores on a standardized mathematics assessment for seventh graders at Jayhawk Middle School:

$$CI_{95} = 70 < \mu < 90.$$

This CI indicates that 95% of random samples taken from seventh graders at Jayhawk Middle School will yield a mean math score greater than 70 and less than 90.

The latter example can also be used to illustrate the role of measurement error in estimating population parameters. Begin by assuming that the CI for seventh graders at Jayhawk Middle School was based on a sample mean that equals the population mean of 80. Furthermore, suppose a random sample of seventh graders from Jayhawk Middle School yielded a mean mathematics assessment score of 81. An additional, independent, random sample taken from the same population of seventh graders at Jayhawk Middle School yielded a mean mathematics assessment score of 77. In both cases, the sample means do not equal the population mean, nor do they equal one another.

The amount of measurement error is used to construct a CI around a particular parameter. This measurement error is referred to as the standard error. The standard error provides a measure of the variability of the sample statistic around the population parameter. For instance, the standard error of the mean is calculated using the following formula:

$$\sigma_{\bar{X}} = \frac{s}{\sqrt{N}},$$

where σ_X is the standard error of the mean, s is the standard deviation of the sample, and N is the sample size. The distribution of an infinite number of randomly sampled means is known to be normal and can be converted to a standard normal distribution. Values can be taken from the standard normal distribution to construct CIs. For instance, a 95% CI requires the use of a standard value of 1.96. This value is multiplied by the standard error of the mean in order to convert the CI to the original unit of measurement. Therefore, the equation for constructing a 95% confidence interval is

$$\bar{X} - 1.96\sigma_{\bar{X}} \leq \mu \leq \bar{X} + 1.96\sigma_{\bar{X}}.$$

As seen in the equation, the product of the standard value and the standard error are subtracted and added to the sample mean to create the lower and upper bounds for the CI.

CIs can also be used to test research hypotheses. The most straightforward hypotheses involve determining if a sample mean is representative of the population. The hypothesized value of the population mean is considered tenable if it falls within the bounds of the CI created by the randomly sampled mean. However, if the hypothesized population mean

does not fall in the CI, the researcher has obtained evidence that the population mean is different from the hypothesized value.

To illustrate this concept, reconsider the example using students from Jayhawk Middle School, where two random samples yielded sample means of 81 and 77, respectively. In addition, suppose a researcher hypothesizes that the population mean score for seventh-grade students from Jayhawk Middle School is 80. For simplicity, assume $s = 2$ and $N = 4$ for both samples, which results in a standard error of 1 for both samples. Using this information, a 95% CI can be constructed for each sample. The 95% CI for Sample 1 and Sample 2 are, respectively,

$$79.04 < \mu < 82.96$$
$$75.04 < \mu < 78.96.$$

The CIs result in different interpretations regarding the hypothesis. In Sample 1, the hypothesized value is contained in the CI, indicating that a mean score of 80 for seventh-grade students from Jayhawk Middle School is tenable. On the other hand, the CI constructed from Sample 2 data does not contain the hypothesized value of 80. Therefore, based on this sample, the mean score for seventh-grade students from Jayhawk Middle School is not equal to 80. In fact, the researcher could state with 95% confidence that the mean score instead falls between 75.04 and 78.96.

In summary, CIs are one of the most prevalent forms of interval estimation used in the behavioral sciences. The width of a confidence interval can give the researcher an idea about the uncertainty in the precision of the parameter that he or she is trying to estimate. For example, a "wide" CI indicates that there is error in the measurement and further data collection should be employed. In addition, CIs are considered more informative than hypothesis tests because they provide a probable range for the unknown parameter.

CONFLICT

Conflict is a disagreement between two or more inter-dependent parties about goals and/or methods for achieving goals. Although some scholars use the term *conflict* to refer to an internal tension or confusion (for example, a mother has "role conflict" when she is torn between competing demands on her time and attention due to her role as a parent and as a working professional), conflict is a social phenomenon concerning disagreements between parties.

A party to a conflict can be a person, a group, an organization, a state, or a nation. Often, conflicts are between two parties who are individuals. But conflict can involve many parties. The more parties to a conflict, the more difficult it is to manage the conflict process and to come to a decision or settlement that is acceptable to all parties.

All parties to a conflict are interdependent; they depend on each other for some action or resource necessary to manage or resolve the conflict. The more one party is needed by the other parties, the more power and influence that party has to define the conflict, determine when and how the conflict is managed, and influence the final outcome or solution for the conflict.

What types of disagreements lead to conflict? Conflicts may be caused by disagreements over scarce resources and how they should be distributed. Scarce resources may be economic, such as money, equipment, and capital; or they can be relational resources, such as status, respect, information, and time. Sometimes, conflicts are disagreements about perceptions that one party is exercising unwanted control over other parties. Conflicts are often disagreements about goals—questions about what should be accomplished and why. Even if parties agree on goals or desired outcomes, they may disagree on the best methods to achieve the outcomes. For example, office managers may agree that they need to upgrade their computer systems, but they disagree about which computer system is the best for their organization.

Conflict can be functional or dysfunctional depending on how the conflict is managed. In functional conflicts, parties are satisfied with both the process used to manage the conflict and the resolution to the conflict. Learning functional conflict management is important for social development and relational development. From early childhood, people learn how to be in peaceful relationships by understanding how to manage conflicts constructively. Many developmental psychologists identify learning to manage conflict constructively as an important skill, and perhaps the most important social skill, of childhood. Educators who work to develop children's emotional intelligence and emotional competence also see constructive conflict management as a key skill for the emotionally competent person. When a conflict is functional, the parties are open and willing to honestly share information, there is a sense of calm and respect, parties are cooperating to try to solve the problem together, and they are flexible in looking at options for solutions.

Dysfunctional conflict happens when a party is dissatisfied with the process or outcome of the conflict. For example, one party may be upset that the other party is unwilling to go to a third party (for example, a mediator) for help with the conflict, or feels the solution to the conflict is unfair. When conflicts become dysfunctional, they escalate in terms of increasingly negative behaviors. Dysfunctional conflicts are characterized by distrust, unwillingness to share information openly and honestly, tension, and the adoption of an "us versus them" attitude that leads to competitive and aggressive behavior. Dysfunctional conflicts often lose focus, and the parties start arguing about issues other than those that initially triggered the conflict. Consider a husband and wife who begin arguing about money and are suddenly arguing about in-laws, parenting, and household chores as well. When conflict becomes dysfunctional, it affects future conflicts. If a person feels he or she was treated unfairly, the person is likely to be defensive and aggressive in the next conflict with the same party.

There are five ways to manage conflicts without the aid of a third party: competition, cooperation, compromise, accommodation, and avoidance. If used in the right situation, all of these techniques or styles can lead to functional conflict. Competition is a win-lose approach, and the goal is to get as much for your side as possible. Competition does not have to be violent or aggressive; for example, buying a car is usually done through bargaining, which is a competitive approach to managing conflict. Cooperation, also called collaboration, is a win-win approach in which parties problem solve and generate solutions that meet everyone's needs. Cooperation is best when there are creative approaches to maximizing gain and when parties must be committed to implementing solutions. Compromise is a give-and-take approach that works well when there are limited resources. However, resources may not be that limited, and cooperation may be the better

approach. Accommodation is letting the other party get what he or she wants in the conflict; this strategy is effective if relational harmony is most important. The danger is establishing expectations that one will usually accommodate. Avoidance is physically and/or psychologically withdrawing from the conflict. For unimportant or short-term conflict, avoidance is a feasible option, but it is counterproductive when the conflict will become worse if not addressed.

Conflict management can also depend on third-party processes such as mediation, arbitration, and adjudication to solve the conflict. Conflict resolution education programs help teach youth and adults constructive ways of managing conflict.

CONSERVATION

Conservation refers to the feature of constancy or invariance of an object. It is the notion that a quantity stays the same despite changes in form or appearance. Educational psychologists study the concept of conservation in children as an important developmental milestone that is reached when a shift in cognitive thinking occurs. One of Jean Piaget's earliest and most important discoveries was that young children lacked the principle of conservation. Much research has been conducted to prove or disprove Piaget's theory of conservation.

While studying how children develop intelligence, Piaget discovered that young children do not understand that quantity, length, or number of items is unrelated to the arrangement or appearance of the items. He developed different tasks to further understand the concept of how children develop the principle of conservation. He looked at mass, number, volume, and area.

For the task of mass, the examiner presents a child with two round balls of clay equal in weight, size, and shape. The child is asked if the two balls are the same weight. The child is allowed to use a balance to assure the weight is equal if needed. The examiner then transforms one ball of clay into a flat pancake or a thin rope. The child is asked again if the two quantities of clay have the same weight and to give and explanation of why or why not.

For the task of number, the examiner presents the child with two equal rows of counters. The rows of counters are arranged side by side in one-to-one correspondence. The child is asked if the two rows are equal. The examiner then spreads one row of coins apart, and again asks the child if the two rows have equal amounts of coins.

The task to assess conservation of volume begins with showing the child two identical containers filled with the same amounts of liquid and asking the child if the amount of liquid is equal. Then, the liquid from one container is poured into a container that is taller and thinner than the other. The child is again asked if the amount of liquid is the same in both containers.

A fourth, less used, and less researched task used by Piaget was the "cows on a farm" test for conservation of area. In this task, two identical farms were presented, each with a cow placed on it. The children were asked if each cow had the same amount of grass to eat. Then, Piaget would add little cubic farmhouses to each farm. On one farm he would line up the farmhouses in a tidy row, on the other farm, he would scatter the farms about on the grass. The child is then asked again if the cows have the same amount of grass to eat.

In each of the above tasks, the child's ability to recognize that certain physical properties do not change, or are conserved, even though they may undergo a physical transformation, is tested. Children who do not understand the principle of conservation will say that the quantity of mass, number, volume, or area has changed.

The ability to recognize the principle of conservation is the dividing line between Piaget's preoperational stage and concrete operations stage. Most

children move from one stage to the next between the ages of 6 and 8.

Piaget believed that children who were unable to conserve mistook a perceptual change for a quantitative change. This confusion could arise from the pre-operational child's tendency to focus or center on only one characteristic of an object to the exclusion of all other characteristics. Additionally, the child's inability to mentally reverse actions is characteristic of pre-operational thought. For example, the pre-operational child cannot mentally reverse the clay-rolling process to determine if the balls of clay are still the same size. A child in the concrete operational stage can understand that nothing has been added or subtracted to the ball of clay. This child can understand that the two dimensions of height and weight are related. The development from pre-operational to concrete operational is a gradual one. A child may be able to achieve number conservation before liquid or mass conservation.

Research regarding Piaget's theory of the principle of conservation has presented information that children may have difficulty with the discourse of the interview that accompanies the conservation tasks. These studies indicate that children may display an understanding of conservation principles earlier than previously thought but misunderstand what is being asked of them by the experimenter. Additionally, some research has shown that with minimal training, competence for the tasks increases.

Other research has pointed that Piaget's tasks are, in fact, testing two different forms of conservation: identity and equivalence. The conservation of identity must be inferred from the child's responses, and the conservation of equivalence can be evidenced in the child's judgments. This means that a child is actually concerned with identity conservation, or how the item looks different but is still the same, but in reality, the child is making an equivalence judgment. But children at this age do not verbalize the actual psychological processes involved in their judgments; instead, they apply logical reasoning.

Conservation is learned through experiences and interactions. The process is gradual and involves developing the ability to focus on more than one attribute of an object at one time, the understanding of reversibility, and the ability to mentally represent objects.

CONSTRUCTIVISM

Constructivism is a learning theory based on the notion that students actively construct knowledge. This view of learning calls for a dramatic lessening of reliance on a didactic, textbook-based, "transmission" of knowledge approach to teaching and learning in the classroom. It also challenges popular views about the nature of knowledge. The fact that constructivism rejects commonplace views about knowledge, however, does not mean that it embraces a relativistic or anything-goes approach. What is also clear is that constructivists who endorse views that oppose the mainstream view—who argue, in other words, that worthwhile knowledge tends to be complex rather than simple, open to question rather than certain—are more likely than acknowledged to promote disagreement among experts about how best to conceptualize knowledge.

Research shows that these core beliefs about knowledge relate to teacher practice, albeit imperfectly, because of the pressures teachers face to cover the curriculum and improve standardized test performance. Another factor that affects teachers as they seek to convert theories of knowledge into classroom practice is that constructivists who argue for a more open approach to teaching and learning disagree about the particulars of the openness. Some constructivists, for example, maintain that the curriculum should be problem based; others argue that it should be based on the students' interest and level of development. The same disagreement arises about the nature of the pedagogy. Some constructivists believe that it should be peer centered; others maintain that it should be individually oriented. A similar disagreement exists with regard to assessment. Some argue that it should be performance based, which is to say, out in the open and judged against a common standard; others believe

that it should be based primarily on each child's progress, best assessed using individual portfolios.

These disagreements about practice among constructivists mirror other, sometimes subtle, theoretical disagreements between different "camps" of constructivists. The disagreements turn largely on the question of what kind of knowledge is most important and how that knowledge is best acquired. Although this may be an oversimplification, one camp of constructivists, the social constructivists, want to move knowledge out of the head and into the open. In this view, knowledge is a community and not an individual possession, a notion that has implications for how members of this constructivist camp define the nature of knowledge. For one, if it really is between people, it has to be overt or observable, which means that knowledge can take two possible forms: It can consist of strategies or routines, or, favored by those social constructivists who consider themselves "postmodern," knowledge can be defined as language.

The two groups of social constructivists, because they define knowledge in two different ways, also hold up different models of learning as being ideal for the classroom. The group that focuses on strategies, strongly influenced by a Russian psychologist named Lev Vygotsky, advances apprenticeship learning as the ideal. The intellectual version of apprenticeship learning can involve a relatively simple strategy such as a mnemonic code (e.g., "one-bun, two-shoe …"), which enables one to visualize an ordered set of objects; or it can involve a complex strategy that encompasses "metacognition" (e.g., planning, monitoring, checking, and revising). Like a veteran tailor, the teacher using this approach is expected to first model the practice, gradually turning over control to the novice as he or she becomes more skillful in implementing the practice.

The second group of social constructivists views knowledge as language, as modes of discourse acquired by participating in what might be considered different types of disciplinary "language games." Language, in this approach, does not hold knowledge; rather, it helps manage or coordinate different kinds of cultural activity (e.g., "doing math"). There is both a process and a content aspect to this coordination. An example of the former might be a teacher who, because she wants her students to discuss ideas in mathematics, models language that depersonalizes the process and thus protects the self (e.g., learns to say, "It is possible that …" vs. "I think that …"). An

example of talking content at the elementary level would be students who, when they are engaged in solving math problems, consistently describe numbers as consisting of units of 10.

The third group of constructivists traces its approach back to John Dewey and, more recently, the Swiss psychologist Jean Piaget. The basic notion here is that children, and adults for that matter, are naturally driven to order or make more coherent the diverse, often fragmentary experiences they encounter each and every minute of their lives. Piaget believed that children develop increasingly complex structures or "operations" over time that allow them to create this coherence. One of the early operations, typically evident in 6-year-olds, allows them to conserve quantity—to understand, for example, that when one compares the amount of liquid in two containers, height can be offset by greater dispersion so that, although the quantity may look different, it may actually be the same. Piaget's view has fallen out of favor, replaced by Dewey's brand of inductionist constructivism. Unlike the traditional didactic approach, often characterized as "the sage (wise person) on the stage" approach, Dewey favors "the guide on the side" approach. The assumption here is that a student can create meaning only by working in his or her own experiential workspace, the 4 or 5 inches of brain between the ears. The role of the teacher is to quietly nudge the process along, to point out in a gentle way any problems the student may be encountering in figuring out how to construe a new experience, to bring to the fore the most important aspects of that experience, and so forth. The type of pedagogy that best fits this view of learning is problem-based, project-based, or inquiry-based pedagogy.

Contingency Contracts

A contingency contract, or "behavioral" contract, is a clearly written document specifying available rewards or consequences that are contingent upon the performance of a certain behavior. The use of a contingency contract is a behavioral management technique that is effective in modifying a multitude of behaviors performed in a variety of settings. A contract is based on simple behavioral principles but provides a complex intervention package. Implementing the key components and procedures outlined in this entry will enhance the effectiveness of a contingency contract.

Contingency contracts have been used in a variety of situations to increase the occurrence of appropriate/desired behavior, healthy behavior, or compliance. These types of contracts are effective in a variety of settings, including classrooms, schools, households, and clinic settings. Many individuals can partake in a contract; however, most contracts include two parties: one party who performs the targeted behavior and one party that grants access to the contingent reward.

Heward and Martin and Pear identify several advantages for using a contingency contract. First, developing and implementing a contract is a fairly simple procedure that is easy to learn and can be completed by non-professionals. Second, a contract provides a socially acceptable and positive behavior management strategy that is individualized for a child or a group of children. Third, a contract directly involves all participating individuals in the behavioral plan and development of the contract. Fourth, using a contract ensures that all participants agree with the behavior and contingent rewards specified in the document. Finally, the act of signing a contract is a powerful stimulus in our society that increases one's commitment to the agreement, thereby enhancing the integrity of implementation and consistency of delivering consequences.

Key Components for Effectiveness

Heward also outlines three major components that should be included in a contingency contract for it to be effective: (1) the *task*, (2) the *reward*, and (3) a *task record*. The *task* portion of the contract includes a description of the task, who is to perform the task (e.g., the role of each participant), when it is to be performed, and how well it needs to be performed in order to receive the reward. The *reward* section includes a description of the reward, who delivers the reward, when it will be delivered, and how much of it will be delivered. A *task record* provides a location on the document where the progress of a contract is recorded. This section for data collection includes records of task completion and reward delivery. Monitoring the progress of a contract serves two purposes: (1) it ensures that all participants are regularly reminded of the contract, and (2) it helps remind the student to continue working toward task completion.

Key Procedures for Effectiveness

A contingency contract is a complex intervention package consisting of both positive and negative reinforcement. Contingency contracts are based on rule-governed behavior, where a specific behavior results in a specific consequence. Heward and Martin and Pear have identified several procedures that make contracts more effective: (a) All participants should have equal parts in the development of the contract. (b) The contract needs to be as clear as possible so there is no confusion about what is required from both parties. (c) The target behavior needs to be clearly defined, observable, and recordable. (d) The parties should identify possible rewards that will motivate the child. (e) Data collection procedures used to evaluate the effectiveness of the contract should be determined, including how, when, and who will collect the data. (f) The relationship between the behavior and the reward should be fair. (g) Each participant must follow the rules set up by the contract. (h) The contract needs to be honest; all participants will comply with the agreement. (i) The contract should be displayed publicly, reminding each participant of the agreement and his or her responsibilities within the contract. (j) Once a clear contract is written and implemented, data should be evaluated for effectiveness. (k) The contract should be altered and rewritten until there is an improvement in behavior. It is necessary to renegotiate the contract after a certain period, even if it was successful.

Contracts in Educational Settings

Contingency contracts have been used effectively in classrooms and school settings. Typically involving a teacher–student contract, these formal agreements have been demonstrated to increase appropriate social

and academic behaviors. As an intervention, contracts between teachers and students have increased student adherence to classroom rules, compliance with teacher directions, work completion, and attendance. A contract is an extremely flexible behavioral management technique: Those established in classroom or school settings can be applied to individual students, small groups, whole classes, or entire schools. Furthermore, rewards can be provided based on individual or group-oriented contingent behavior.

Behavioral interventions using *home-school notes* are essentially contingency contracts between a child, a teacher, and a parent. They have been used to effectively modify classroom (i.e., on-task behavior) and home behavior (i.e., homework completion). There are several advantages to contingency contracts that involve individuals from both home and school. First, they allow teachers to utilize reinforcers not typically present in classrooms. Second, they enhance consistency between the two most important settings (i.e., home and school) in a child's environment. Third, they facilitate the development of home-school partnerships that are beneficial for the academic, behavioral, and social development of children.

Another type of contracting that is useful with children in educational settings is a *self-contract*. Self-contracting is a way to teach children self-management strategies. It is a self-directed method of problem solving, one that offers an opportunity for the students to take responsibility for their behavior. Included in self-contracting are the following steps: (a) self-identification of target behavior, (b) self-monitoring of behavioral performance, (c) self-evaluation of performance, and (d) self-administered consequences based on contingency.

Limitations of Contracts

Contingency contracts operate within a delayed reward framework; the reward can be perceived as far removed from the behavior targeted. Thus, contracts may be less effective when used with students who are very young or who have extremely little motivation. This is especially true when the contract requires the performance of a behavior over a period of sequential days in order to earn a reward. Other limitations include teacher and parent perceptions of using contracts. First, teachers and parents may view contracts as requiring too much time to implement or as being too complex. Additionally, they may perceive

a contingency contract as a behavioral modification technique that reduces the degree of responsibility children have for their own behavior.

CONTINUITY AND DISCONTINUITY IN LEARNING

Continuity and discontinuity in learning refer to the problem of whether there are qualitative changes in the fundamental mechanisms that govern learning. This question has been examined in the literature in two separate but related ways. The first approach examines whether qualitative breaks occur with increasing expertise or additional learning, and it was conducted mostly prior to the 1980s using animal learning paradigms and human learning of simple verbal materials. The second approach evaluates whether there are developmental changes in learning that are qualitative in nature.

The historical debate was inspired in part by the observation of seemingly contradictory phenomena. On one hand, much research in learning, including the seminal results from Hermann Ebbinghaus, revealed canonical smooth learning curves, in which performance could be plotted as a negatively accelerating approach to an asymptote. On the other hand, research by Robert Yerkes and Wolfgang Köhler using primates appeared to reveal "insight" in basic problem-solving tasks. Complementing these reports

were results from learning in rodents in which learning appeared to hover quite stably around chance levels of accuracy prior to rising rapidly to an asymptote. Even in tasks in which learning appears continuous, theorists such as William Estes and Randy Gallistel have shown that the learning functions for individual subjects may exhibit a more abrupt rise in performance than is comfortably accommodated within a view of learning that is purely continuous.

This dilemma motivated empirical and theoretical demonstrations from notable researchers like Kenneth Spence and Isadore Krechevsky (later David Krech) that continuous and gradual learning processes could underlie the apparently discontinuous learning curves that appeared to imply underlying learning processes that were more all-or-none than continuous. Such considerations probably played a large role in the sea-change in American psychology from stimulus-response theories to the mentalistic types of theorizing characterized by the work of Edward Tolman—theories that included previously taboo terms such as *hypothesis generation and testing* and *insight*, and that eventually became known as the cognitive revolution from the 1950s to the 1970s.

During that latter period, questions of continuity inspired one of the first widespread applications of basic mathematical models of psychological processes to questions about learning. The burgeoning set of researchers who pioneered the application of Markov processes to cognition, including William Estes, Patrick Suppes, James Greeno, and Gordon Bower, found that smooth learning curves could be produced by all-or-none learning functions, and that those all-or-none models accounted well for verbal learning data in humans. Two related empirical outcomes are central to the claim of supremacy for all-or-none models.

First, Estes showed that people tend not to recall items correctly on a second test when they have not correctly recalled them on a previous test. If discontinuous learning actually arose from variable levels of underlying learning, rather than the pure absence of learning, then an above-chance rate of recovery for previously unrecalled items would be expected. Second, there is no increase in memory performance with additional learning when only those trials prior to the final error for a particular item are examined. This, too, is consistent with the idea that those items reside in an as-yet unlearned state, rather than a state of

gradually increasing learning that is nonetheless insufficient to support accurate performance.

However, the validity of these data and of the all-or-none models was questioned, and other data appeared to contradict the central results. For example, giving subjects an opportunity to guess again when they have made an error leads to a violation of the "stationarity" principle represented by the second finding described above. The lack of a clear resolution can be best understood in light of the insights of Frank Restle, who pointed out that numerous versions of the continuous/discontinuous debate were in play, and that theorists were debating on incompatible terms. A summary of the literature prior to the mid-1960s revealed that, although it is quite clear that much learning is incremental, it is also evident that some learning is more likely of an all-or-none flavor. Given the many ways in which discontinuous processes can mimic continuous ones, and vice versa, it is not evident that a deep theoretical resolution to this issue is forthcoming. However, from an educational perspective, it is worth remembering that the progression of learning may have as much to do with the nature of the task as with the nature of the learning process: Tasks in which information can be acquired incrementally are more likely to yield continuous learning functions than are tasks for which mastery hinges on the acquisition of a single principle or rule.

A related issue of continuity has been evaluated within developmental or lifespan approaches to understanding cognition: Does maturity induce qualitative changes in the mechanisms of learning? Indeed, much of the work in cognitive development and geriatric cognition can be characterized as a debate over which learning processes develop when, and which ones selectively decline with age. What is not in dispute is that there are qualitative changes in the patterns of results seen on tests of learning and memory. The elderly exhibit, for example, a much greater deficit relative to young learners on tests of recall than on tests of recognition. Fergus Craik has proposed that elderly learners will show, in general, deficient performance on tests that require them to self-initiate processing and relatively intact performance on tests that place little demand on such self-initiation. Tests of recall, which require the subject to develop and execute a systematic plan for addressing memory, retrieving relevant information, and outputting it successfully, play to the weaknesses of the elderly. Tests of recognition, which elicit only small deficits,

do not place a premium on self-directed processes but rather emphasize simple, presumably automatic, mechanisms.

Despite these results, it is not clear whether the underlying learning mechanisms actually differ between people of different ages, or if the apparent discontinuities arise epiphenomenally. Older learners may suffer more from proactive interference than younger learners, not because fundamental mechanisms differ, but rather because they have many more years of experience to interfere with learning and memory. If a constant amount of proactive interference affects different tests or tests for different types of information differentially, then empirical test dissociations can appear between age groups without a change in the underlying cognitive processes.

COOPERATIVE LEARNING

Cooperative learning is an instructional process that engages students in collaborative discussions about the content to promote learning. The discussions may involve teaching, explaining, asking questions, quizzing, or checking, in an instructional activity where students actively share in the responsibility for learning. Cooperative learning processes significantly restructure classrooms from passive learning environments, with the teacher dominating the instructional conversation, into engaging environments where students actively participate in the learning environment.

Cooperative learning also attempts to change the social and motivational environment in the classroom to promote positive and supportive peer interactions and a positive orientation toward achievement and learning. This selection on cooperative learning will describe the philosophical and historical roots of cooperative learning. It will describe the theory behind the positive effects of cooperative learning and finally discuss some of the common cooperative learning methods used in elementary, secondary, and college instruction.

In many forms of cooperative learning, teachers initially lead instruction as a way to communicate new information or skills to students. As the students practice the new learning, the teacher guides them to develop more proficiency. Gradually, the students take the instructional lead as they interact with peers practicing collaboratively. This type of transfer of responsibility for learning, from the teacher increasing gradually to the students, is characteristic of most forms of cooperative learning.

There is an important distinction between cooperative learning and more traditional group work. Cooperative learning has structural features that are important to determining how the students work within the group and the effects that cooperative learning has on both academic and social outcomes. Most researchers believe it is important for well-structured cooperative learning to have a group goal and individual accountability. The group goal is the reason for the group members to collaborate; it motivates the students to work together and creates the interdependence necessary for a well-functioning group. Some examples of group goals include a written report, a product for a project, or an average test score for the group. The individual accountability is the reason for each group member to learn, and it is critical for the positive academic benefits found in cooperative learning research. The individual accountability ensures that each member of the group does his or her share of the work. Well-structured cooperative learning differs greatly from traditional group learning in large part because group work did not necessarily include individual accountability. For example, it is possible for one person in the group to write the whole report or to do most of the problems in the group activity. This kind of group work is less likely to lead to the kind of positive social and academic effects found in the research on cooperative learning.

Historical Background

Cooperative learning is not a new idea in education. Certainly, one of the early uses of cooperative learning occurred in the one-room schoolhouse, where one teacher was forced to teach students with a very wide range of abilities and ages. It is likely that teachers used collaboration among students as a pragmatic response to a challenging teaching situation. The philosophical notion of learning through peer collaboration is seen much earlier, in the writing of Quintilian (1st century) and Comenius (17th century), up to more recent work by John Dewey (20th century). All discuss the potential benefits of students teaching and learning from one another, yet it is unclear whether any of these earlier conceptions of cooperative learning took hold in the educational settings of the day.

Current applications of cooperative learning trace its development to sociology and social psychology in the mid-20th century, specifically to Gordon Allport's Social Contact Theory and Morton Deutsch's studies of group dynamics. While studying racial prejudice in social settings, Allport found that prejudice was reduced in settings where racially diverse people had close, substantive contact while working to achieve a common goal. The quality and depth of the racial interaction was an important factor in reducing racial prejudice. This became an important issue as public schools in the United States began the long task of desegregating, and overtly prejudiced behavior and poor peer relations were typical in newly desegregated schools.

Similarly, Deutsch's work provided social psychological support to this theory. In his work on competition versus cooperation, Deutsch found that in cooperative settings, where an individual's success was dependent on the success of others, individuals engaged in more positive communication with one another. These positive and supportive communication patterns led to groups with higher productivity and significantly more positive peer relations. This contrasted with the findings that competitive environments led to less group cohesion, fewer facilitative interactions, and generally less positive peer relations.

Social Outcomes of Cooperative Learning

These social psychological developments became of particular interest to educational psychologists in the 1960s and 1970s as research in desegregated schools found that racial prejudice and segregation within the schools were prevalent. Researchers applied social contact theory to the problem of diminishing prejudice and poor peer relations in newly desegregated schools. Early work on cooperative learning models such as Jigsaw and Teams Game Tournament attempted to put students together in groups to collaborate on common goals in an attempt to engage them in the kind of substantive contact that Allport had noted reduces prejudice. The research by Elliott Aronson, David DeVries, Robert Slavin, and David Johnson found that cooperative activities that engaged students of different races and backgrounds in substantive, academically oriented dialogue decreased prejudice and increased the quality of peer relations. The effects of cooperative learning on improving peer relations were found to transfer to relations outside the classroom, and positive peer relations remained during the school year even after the cooperative learning activities were over.

Academic Outcomes of Cooperative Learning

As cooperative learning research became more prevalent in schools, researchers noticed significant increases in academic performance among the cooperative groups. This was a natural extension of Deutsch's previous work on group dynamics as the group's positive and supportive communications led to higher productivity. Initially, the research on academic benefits used generic models of cooperative learning like Student Teams Achievement Division (STAD), Jigsaw, Learning Together, and Group Investigation (all described below). These models engage students in cooperative learning processes where they interact collaboratively on academic content. The models are not content specific and can be used with almost any instructional content. Typically, teachers use them as periodic activities to facilitate learning the content, often as an interactive way to practice the content or skills.

Similar research on student learning in university settings has also found academic benefits of cooperative learning. Researchers such as Alison King, Donald Dansereau, and Angela O'Donnell have found that peer collaboration during lecture and while reading textbooks can improve students' learning and retention of the content being presented.

Over time, some cooperative learning models became closely connected with specific content, becoming an instructional process integrated into daily instruction rather than an add-on activity that students engaged in periodically (e.g., weekly). Content-specific models of cooperative learning include Reciprocal Teaching and Cooperative Integrated Reading and Composition in reading and language arts, and Team Accelerated Instruction in mathematics. These content-specific models were found to have similar advantages for student learning.

The Nature of Cooperative Dialogue

For cooperative learning to be effective in promoting achievement, the cooperative dialogue must go beyond the "facilitative communication" first described by Deutsch. Research has found that not all student help is effective in increasing the achievement of both members of the dyad. Peer communications that result in terminal responses, where one student simply tells the answer to the other student, do little to increase the learning of either the student who gives the response or the student who receives the response. On the other hand, when a student provides an explanation as a response, like telling how to find the correct answer or explaining why an answer is correct, both students are likely to benefit from the experience. Receiving an explanatory response helps a student learn or encode something he or she previously did not know. More importantly, giving an explanation helps the other member of the dyad to process what he or she has learned in his or her own words, making more connections between the new information and his or her prior knowledge and enhancing understanding. Some research has suggested that the students who provide elaborative explanations actually experience greater achievement benefits than their peers who receive the elaborative explanations.

Multiple Theoretical Rationales for Cooperative Learning

A number of theoretical rationales have been used to develop and explain cooperative learning activities. As described above, the earliest rationale was based upon sociological theory relating to social contact and social psychological theory relating to group dynamics. These theories predicted and explained the positive social outcomes found in early cooperative learning research; however, the theories did little to explain the learning outcomes.

Generative Learning Theory

Perhaps the most prevalent theory for explaining cooperative learning's academic effects is generative learning theory. Generative learning suggests that when learners explain something to someone else in their own words, they increase their understanding of what they explain. Generative learning is situated within the information processing model of cognitive learning theory and specifically focuses on the processes involved in the activation of prior knowledge so that new knowledge is integrated with previously learned knowledge, thus increasing the probability of comprehension and recall of the new knowledge. This theoretical view explains the importance of giving elaborative explanations during cooperative learning to promote learning for not only the student who receives the explanation, but also for the student who gives the explanation. Generative theory provides a rationale for the evidence that high-ability students gain as much or more academically from cooperative learning as do average- or lower-ability students. Although common knowledge would cause one to expect lower-ability students to have the greatest benefits from cooperative learning processes, generative learning theory helps to explain why this is not necessarily the case.

The generative learning benefits during cooperative learning depend on students explaining or elaborating to one another; thus, teachers must monitor the interactions to make sure students provide explanations and do not provide terminal responses. Teachers also need to ensure that all students, regardless of ability, have an opportunity to provide elaborative explanations. To some extent, research has found that scripting interactions where students alternate roles in the elaborative dialogue can remedy the issue of equal opportunity to engage in the generation of explanations.

Sociocultural Learning Theory

Other cooperative learning research uses sociocultural theory and Lev Vygotsky's work to explain the academic effects of cooperation. Vygotsky suggests that development and learning occur as individuals internalize new information and skills, those within the proximal zone of development. In particular, Vygotskian theory states that for complex cognitive tasks, learners benefit

from interactions with more competent peers, like those interactions in cooperative learning. The theory suggests that interaction facilitates the internalization of newly learned skills. This type of interaction has also been called a cognitive apprenticeship, where learning occurs while engaging in academic interactions with a more competent peer or adult. The theory offers an understanding of the broader sociocultural context of cooperative learning, yet it may not fully explain the learning processes involved.

Sociocultural theory revolves around the ability of peers to provide guidance and feedback to one another during the collaborative dialogue, and their ability to do this effectively may depend on the age and sophistication of the students. Researchers have found that directly teaching, guiding, and monitoring students in how to engage in collaborative dialogue increases students' capability of providing these kinds of interactions.

Piagetian Learning Theory

Piagetian theory has also been applied to understanding the effects of cooperative learning, specifically through the concepts of construction of knowledge and cognitive conflict. The theory suggests that contradictory views, such as those that might occur in cooperation with a peer, create cognitive conflict. Piagetian theory suggests that cognitive conflict results in disequilibration that drives the learner to attempt to solve the internal conflict and hence construct meaning. Cooperative learning creates social interactions in which cognitive conflict occurs, and where continued collaborative dialogue (e.g., elaborative explanations) leads to conflict resolution and cognitive re-equilibration. The theory suggests that in cooperative learning, the interactions with peers stimulate this cognitive process that in turn increases learning of new information and skills.

This type of cooperative learning puts a premium on students learning how to work together in attempts to solve problems and resolve disagreements. Team-building activities are essential in order for groups to have sufficient cohesion and conflict resolution skills to work through their disagreements and collaborate in their investigations. The teacher's role is to promote team building and to act as a facilitator in guiding learning through investigation.

Sociocognitive Learning Theory

Albert Bandura's sociocognitive theory has also been used to explain the impact of cooperative learning processes on students' learning. Sociocognitive theory suggests that the learner will benefit from models in the environment, such as interacting with peers to promote both learning and motivation. At the same time, the theory suggests that the learner will reciprocally influence the group in the process, through goal setting, self-efficacy, and self-regulation during the cooperative processes. The reciprocal influence in this theory helps to explain many of the influences in peer collaboration; however, the internalization of learning, although mentioned, is not explicated.

To a great extent, these theories are not incompatible with one another, nor do they contradict one another in attempting to explain and describe the effects of cooperative learning on learning. Instead, they offer different foci in attempts to explain the nature of cooperative learning processes and the learning processes they promote. Because of their different foci, no single theory seems to capture all that is important about learning during cooperative interactions. Each offers a somewhat different insight into cooperative learning processes.

Selected Cooperative Learning Methods

There are a variety of methods for integrating cooperative learning into classroom instruction. The methods reflect differences in theoretical perspective, student population, or the nature of the instructional content. This list is by no means all inclusive; it is only intended to provide descriptions of methods to show the variety of different ways cooperative learning has been applied to classroom instruction. The initial models will be generic models that are cooperative learning processes that can be applied to a wide range of content. The latter models will be content-specific models specifically designed for use in one content area.

Jigsaw

Jigsaw is one of the earliest models of cooperative learning processes, and it was developed by Elliott Aronson. Jigsaw is best used with students in elementary school through college for learning narrative content (e.g., learning from a chapter in a text, doing a research report) and when the goal is content knowledge rather than skills. Teams are typically made up of four members. Members are assigned a portion of the

content that they are to research and learn so they can teach it to the other students in the team. In essence, they become the experts in that content. All of the students who are to become experts in the same content meet and work together on the important information for their area. After they have gathered the information, each expert returns to his or her team and teaches the content to the other students. In this way, each student has an opportunity to teach and elaborate on a portion of the content to his or her peers.

Student Team Achievement Division (STAD)

STAD is a cooperative learning method developed by Robert Slavin that is used in learning factual content (e.g., vocabulary, social studies or science information) as well as discrete skills (e.g., spelling, math computation, or language mechanics skills) for students in second through twelfth grade. Typically, it is used near the end of a unit of instruction and is used to promote active student practice in preparation for a test on the content. In STAD, the students are assigned to heterogeneous teams composed of four or five students. Initially, the teacher computes a base score in the content for each student, using a previous test(s) or a pretest. As students begin preparing for the end-of-the-unit test, they quiz one another about the material they are learning. Students then take the test, which is used to determine their grade and to determine their improvement points. Improvement points are based on the amount by which the student's performance increases above his or her previously computed base score. Improvement points are then used to calculate team scores for use in recognizing teams with good overall improvement. A large quantity of research on STAD consistently shows its positive effects on achievement and peer relations.

Teams Game Tournament

Like STAD, Teams Game Tournament (TGT) is used to promote students' learning of factual content or discrete skills, and is typically used near the end of a unit of instruction. In TGT, students from heterogeneous teams play an academic game, or tournament, that involves answering questions about the content, competing against three students of similar ability from other teams. The tournament involves students taking turns answering questions on the content. The other two students in the tournament can challenge the

student if they think he or she is incorrect. For every question the student answers correctly, the student gets a point. The points are used to calculate team scores, which, like STAD, are used for team recognition.

Group Investigation

Group Investigation is a cooperative learning method developed by Shlomo Sharan and Rachel Hertz-Lazarowitz in Israel that focuses on developing social skills and positive peer relations while learning academic content. The method is essentially cooperative inquiry, where students acquire, analyze, and synthesize information to solve a problem (e.g., write a research report, develop a plan of action). The groups work together to use resources such as texts, reference materials, and technology resources to collect relevant information. They then discuss how to organize the information for use in solving their specific problem. The teacher acts as a facilitator and guide, directing students to various information resources and asking them questions to guide their problem solving. At the end, each group presents a report of its work to the entire class. Research has shown that Group Investigation is particularly effective in increasing peer relations and developing students' interpersonal skills.

Learning Together

The Learning Together cooperative method developed by David Johnson and Roger Johnson is used in elementary and secondary school. The method emphasizes face-to-face interaction, positive interdependence, individual accountability, and interpersonal skills. Typically, Learning Together involves team building and teaching students appropriate interpersonal skills to facilitate the cooperative learning process. Some of the Learning Together methods have students study content together and quiz each other in preparation for individual tests. Other Learning Together methods involve students working together to complete a group test. Research on Learning Together has consistently indicated improved interpersonal relations and acceptance of peers.

Guided Reciprocal Peer Questioning

Guided Reciprocal Peer Questioning (GRPQ) is a cooperative learning method developed by Alison

King that was used initially with college-age students. Subsequent research has shown it can also be used effectively with children in the upper primary grades. GRPQ is used to help students actively process content presented in a narrative fashion, either in a textbook or from a lecture. Students are taught to ask questions about the content based upon question starters like "What does ____ mean?" "Describe ____ in your own words." "Explain why _____." Students ask a question to a partner, who attempts to answer it and then reciprocates by asking another question. This process can be used as students read a section of a textbook, or during a lecture when the instructor periodically stops to allow students to ask questions of a peer. Research has shown that students who use this method retain more information they read or hear in lecture, and it promotes metacognitive skills as students learn to ask themselves questions either during reading or when listening to a lecture.

Cooperative Integrated Reading and Composition

Cooperative Integrated Reading and Composition (CIRC) is a cooperative learning approach to teaching reading and language arts developed by Robert Slavin and Robert Stevens. CIRC has been used with students in second through fifth grade, and a companion model, Student Team Reading and Writing (STRW), has been used in middle school literacy instruction. CIRC is a multifaceted approach that involves students in learning both factual content (e.g., new vocabulary) and skills (e.g., reading comprehension and writing). The teacher provides initial instruction that is followed by students practicing collaboratively to complete tasks such as developing vocabulary knowledge, developing comprehension of the story, extending story comprehension through writing about the story, and engaging in the writing process for creative writing activities. Students check factual knowledge, make and elaborate on predictions, and provide clarifying explanations to one another about what they are reading. At the end of the instructional cycle (e.g., weekly), the students take tests, and the points earned on the test are used for team scores that are used for team recognition like that described above in STAD. Research studies have shown that CIRC and STRW have significant, long-term, positive effects on students' achievement, attitudes, and peer relations.

Reciprocal Teaching

Reciprocal Teaching is a cooperative learning method developed by Annamarie Palincsar to improve reading comprehension skills for students in elementary and middle school. Reciprocal Teaching begins with the teacher providing explicit instruction on comprehension strategies related to questioning, clarifying, summarizing, and predicting as students read. The teachers follow the initial instruction by guiding students as they practice using the strategies by prompting them with questions that they answer. Over time, the students take more responsibility by using questions to prompt one another; the questions are followed by answers in a reciprocal dialogue. The teachers monitor and guide the dialogue, helping the students increase their accuracy and proficiency in using the comprehension-fostering strategies. Research provides evidence of the efficacy of Reciprocal Teaching for students from third grade through middle school, with particular emphasis on struggling readers. Students also maintain the benefits of Reciprocal Teaching after the conclusion of its use in instruction.

Team Accelerated Instruction

Team Accelerated Instruction (TAI) is a cooperative learning approach to mathematics instruction developed by Robert Slavin for use in elementary and early middle grades. TAI focuses primarily on teaching math computation skills in a way that allows students to move at their own pace as they master each skill. The teacher begins the instructional cycle with an ad hoc instructional group based on those students beginning that particular unit. Following the initial instruction, the students engage in practice activities to develop mastery of the new skills. Students work in heterogeneous teams, allowing team members to give feedback and explanations to one another as they practice. There is ongoing progress monitoring as students take periodic tests to assess mastery. Students also earn points for their team by the number of instructional units they master and their level of performance on the mastery tests. Team points are used in determining team recognition like that in STAD, described above. Research indicates that TAI improves students' mathematics achievement and interpersonal relations for students of all abilities in second through sixth grades, and remedial secondary mathematics.

Across cooperative learning methods, there is remarkable consistency in how cooperative learning can positively influence academic and social outcomes in instruction across a variety of grade levels.

CORRELATION

Correlation is a descriptive statistical technique whereby the relationship between pairs of variables is assessed. The strength of the association between two variables can be determined either qualitatively, with a scatterplot, and/or quantitatively, with a correlation coefficient. A scatterplot is a two-dimensional graph with one variable plotted on each axis, whereby the slope of the least squares regression line (i.e., a linear "fit" through the maximum point cluster) indicates the overall direction and strength of the association. If the linear trend of ordered pairs is sloped upward (downward) from the origin and toward the right, the correlation between the two variables is positive (negative); no slope indicates a neutral relationship, and the variables are unrelated. The closer the data points cluster to this line, the stronger the association between the two variables.

The most common quantitative measure of correlation is the Pearson product-moment correlation coefficient, or simply Pearson's correlation (r), expressed as the ratio of the covariance between two variables to the product of their individual standard deviations. Pearson's correlation assumes a linear relationship for the variables under consideration and that the data are of ordinal or ratio scale and normally distributed. Correlation values range between -1.00 and 1.00, with more positive (negative) values indicating a stronger, direct (inverse) relationship and those values closer to zero signifying that the variables are not linked. The categorization of the strength of correlation coefficient values varies by discipline and inquiry. Typically, meaningful r values in the behavioral sciences are in the order of $|0.60 - 1.00|$ for strong, $|0.59 - 0.40|$ for moderate, and $|0.2 - 0.39|$ for weak associations. The researcher must evaluate the correlation coefficients with caution as an association between two variables does *not* equate with causation, and, in some cases, spurious relationships may be found between variables that defy logical explanation.

To test whether or not a correlation coefficient is significant, the t-test statistic is the most common measure used, especially for sample sizes smaller than 30. The t-test is the ratio of the Pearson's correlation coefficient (r) to the standard error of the estimate, a measurement of the variability of sample means. The t-test scores are often converted to probability values (p values), which identifies the probability of erroneously rejecting the null hypothesis if it is, in fact, true (i.e., a Type I error). Significant p values are typically those that are less than 0.05, indicating a 95% (or greater) confidence interval and, thus, the probability of making a Type I error less than 5%. In the case of a significant t-test, the null hypothesis that the two variables are independent (i.e., not correlated) must be rejected and the alternate hypothesis that the variables are related should be accepted. Based on the tail of the probability distribution, the alternate hypothesis is designated as either one-tailed (directional) or two-tailed (nondirectional), the latter being more appropriate if there is no a priori knowledge on the direction of the correlation between the two variables.

The use of Pearson's product-moment correlation coefficient in educational psychology is illustrated in the following example. Suppose a researcher wanted

to examine the relationship between the verbal test score portion on a standardized college entrance exam and number of hours spent in preparation for a group of students ($n = 50$). To interpret the correlation coefficient examining this relationship, the researcher should inspect both the sign (i.e., positive or negative) and the magnitude of the correlation. If the correlation coefficient is high and positive (e.g., .78), that means that those students who score high on the verbal section of the test are very likely to have spent more hours in preparation than other students. If the correlation is close to zero (e.g., .08), then there seems to be no direct relationship between the test score and how long the students prepared. Finally, if the correlation is high and negative (e.g., $-.62$), then the students who prepared more are not likely to do as well on the test as those who prepared less.

If the association between two variables is considered to be influenced by a third or more other variables, then partial correlation is employed. This technique is used to clarify bivariate relationships by removing (or partialling out) the confounding effects of other, possibly related variables. If the correlation coefficient between two variables remains unchanged while holding all other variables constant, then the control variables do not have any influence on the relationship. Conversely, large differences between the original Pearson's correlation and the partial correlation indicate that the relationship between the two variables is spurious and they are not directly linked, thus associated only by mediatory variables. In the previous example, the relationship between verbal test scores and study hours may be influenced by a third variable, such as whether or not English is the student's native language.

If the assumptions of Pearson's correlation are violated (i.e., not normally distributed, nonlinear relationship), a nonparametric correlation statistic, such as Spearman's rank [or Spearman's rho (ρ)] or Kendall's tau (τ) correlation coefficients, may be a more suitable alternative. Spearman's rho, the more common of the two methods, measures the strength of the association of ordinal (or reduced to ordinal) data by examining the ratio of the sum of the squared differences in the ranks of the paired data values to the number of variable pairs. Alternatively, Kendal's tau evaluates the linkage by examining the proportion of discordant pairs in a sample, where pairs are considered discordant if the product of the bivariate observations is negative. As with Pearson's correlation, coefficient values range

from -1.00 to 1.00 and are interpreted similarly, with larger values indicating a stronger relationship between the two variables.

In large samples, the coefficient values of both of these nonparametric test statistics are nearly identical; however, in the case of smaller sample sizes, Kendal's tau is usually the more efficient test.

CREATIVITY

Creativity is among the most valued yet least understood of educational psychology constructs. For the purposes of this entry, *creativity* is defined as the interaction among aptitude, process, and environment by which an individual or group is able to produce *original* (unique, novel, unusual) and *adaptive* (useful, appropriate, meaningful) interpretations, ideas, behaviors, solutions, or products. Although most people view creativity and originality as synonymous, creativity scholars have emphasized the importance of including the additional criterion of *adaptiveness* in definitions of creativity. Without this added criterion, anything merely unusual would also pass as creative. Confounding creativity with uniqueness has, in part, resulted in the perpetuation of various misconceptions of creativity (e.g., creativity requires elimination of constraints and rejection of standards and conventions) and negative associations with those who are creative (e.g., creative individuals suffer from psychological disorders).

The Adaptiveness Criterion

Creativity researchers have demonstrated—in case studies of eminent creators and investigations of everyday forms of creative expression—the importance of including the criterion of adaptiveness in definitions of creativity. The adaptiveness criterion distinguishes creativity from novelty and provides a context for

evaluating particular contributions. Consider the every-day creativity of developing a new recipe. No matter how novel the combination of ingredients (e.g., oxtail, dandelion stem, maple syrup) or the technique (flambé)—if the resulting meal is inedible, then the recipe would hardly be considered creative. Rather, in order for the meal to be considered a form of creative expression, it would need to be original and useful.

The importance of adaptiveness is also illustrated in eminent forms of creative expression. Creativity scholars have documented that the highest forms of creativity typically require a deep understanding of the conventions and traditions of a particular domain: usually 10 or more years of formal study or apprenticeship. For example, eminent, creative jazz musicians (e.g., John Coltrane, Charlie Parker, Miles Davis) not only had an amazing ability to create highly original compositions, arrangements, and improvisations, but they were able to do so because of their deep knowledge and mastery of musical standards and instrumental techniques.

Sociocultural Context

In addition to recognizing the combined importance of originality and adaptiveness, creativity scholars also have stressed the importance of the sociocultural context in their definitions of creativity. This emphasis on the role of context has moved conceptions of creativity beyond traditional individualistic perspectives, which represent creativity as a static, genetically predetermined trait. Rather, most contemporary definitions of creativity emphasize the role that the sociocultural (and, at times, historical) context plays in determining what is considered original and adaptive. This is particularly the case with the most eminent creators. For example, case studies of great creators (e.g., Johann Sebastian Bach) highlight the role that the sociocultural context (e.g., the judgment of historians, critics, connoisseurs, and subsequent musicians) has played in determining the originality and adaptiveness of some creative body of work (e.g., Bach's musical compositions posthumously deemed highly creative).

The sociocultural context also plays a key role in more ubiquitous examples of creative expression. For example, in order for an architectural design to be considered creative, it must be judged to be not only original by the gatekeepers of the domain of architecture (i.e., professors of architecture, professional architectural societies and associations, historians,

fellow architects), but also adaptive (i.e., fit in with the standards and conventions of that domain, be structurally sound). Similarly, although a high school student's spoken-word poem may not be considered sufficiently original or adaptive to be included in the *Norton Anthology of Modern Poetry*, the student's poem might very well be considered creative within the context of her high school classroom, after-school poetry club, or local poetry event.

Common Misconceptions About Creativity

Like any construct that has wide appeal, popular beliefs about creativity have resulted in the development and persistence of several misconceptions. Three common misconceptions with particularly important implications for educators have resulted from confounding creativity with negative deviance, the arts, and eminence.

Creativity and Negative Deviance

The myth that creativity involves some degree of socially negative deviance is the upshot of believing that creativity represents a form of unconstrained novelty. In a classroom context, this misconception typically is represented in teachers' believing that if they encourage students' creative expression, they will ultimately take their class off topic by deviating from curricular standards, which will likely result in confusion or other classroom disruptions. It is not that teachers fail to see value in student creativity (in fact, most view creativity as important); rather, they struggle with how they can legitimately justify the incorporation of something in their standard curriculum that they believe will take instructional time away from learning the content. Not surprisingly, then, many teachers come to view creativity as extracurricular and not appropriate for their regular classroom instruction.

Creativity and the Arts

When most people think about creative expression, they often think of the visual or performing arts, and teachers are no exception. Consequently, teachers may struggle with the idea that creativity should be a common feature of their curriculum. If teachers believe that the visual or performing arts are the only form of creative expression, then it is easy to imagine

how creativity would come to be viewed as a rare, extracurricular luxury (e.g., having the students don costumes and perform the key elements from a historical description of the Salem Witch Trials, or having students write Haikus while studying the seasons). Although likely entertaining (and perhaps engaging), such representations of creativity have little to do with "creativity" as modern scholars conceptualize it.

Rather, many researchers highlight the importance of teachers helping students recognize and develop their creativity in various academic domains (e.g., scientific creativity, creative writing, artistic creativity). Incorporating creativity in the curriculum, from this broader perspective, would involve emphasizing the importance of developing novel ideas and products within the context and conventions of a particular academic domain. For example, a seventh-grade science teacher might support and encourage the development of scientific creativity in students' conceptualizations of their science fair projects. In order to do so, the teacher might require his or her students to develop a novel project idea (meeting the originality criterion of creativity) as well as adhere to the conventions and standards of scientific inquiry (meeting the appropriateness criterion of creativity). The creativity of such projects would then be judged within the sociocultural context of that particular science fair (by teachers, peers, guest judges, and other relevant stakeholders).

Creativity and Eminence

Finally, a common and damaging misconception is that only certain people can be creative. This belief is reinforced by the attention given to the revolutionary breakthroughs often attributed to a few creators (e.g., Wolfgang Amadeus Mozart, Mohandas Gandhi, Albert Einstein). It is true that the odds of a teacher having a classroom full of potential Martha Grahams or Martin Luther King, Juniors are slim to none. However, it does not then follow that teachers need not be concerned about supporting and enhancing students' creative potentials. As most researchers now recognize, all students have creative potential (although not necessarily on the level of magnitude of the rare, eminent creator). And although a few students will always demonstrate unusually high potential and creative ability and likely would benefit from additional curricular enrichment and acceleration, all students stand to benefit from having their creative potential recognized and supported.

Viewing creativity from a developmental perspective (with various degrees of creative magnitude) may help teachers recognize that all students have creative potential. For instance, creativity scholars have demonstrated how the creative life typically follows a trajectory starting with intrapersonal creative interpretations (referred to as mini-c creativity) moving to socially recognized forms of creative expression (little-c creativity), and, in very rare instances, going on to make revolutionary contributions that have lasting, historical, and cultural significance (Big-C Creativity). Big-C Creativity represents the highest forms of creative expression, whereas little-c represents the more ubiquitous, everyday forms of creativity. A great deal of scholarship has been focused on the Big-C level of creative magnitude and has yielded important and compelling insights. For instance, scholars who have conducted research on Big-C Creativity have demonstrated through case studies (i.e., in-depth studies of eminent creators) and histrometric methods (i.e., the quantitative, historical studies of general trends in creativity across time) that eminent levels of creativity result from a confluence of factors (e.g., motivation and skill, past and present environmental supports and constraints, the current and future sociocultural-historical context, and even luck).

The scholarship on Big-C Creativity provides an important backdrop for understanding the extremely rare and revolutionary impact that creativity can have on the development and advancement of science, technology, the arts, and societies as a whole. However, little-c creativity is often more relevant and important for educators to understand as it refers to the everyday forms of creative expression thought to be accessible to almost anyone (e.g., students designing a unique and accurate solution to an everyday science problem; students expressing their frustration about some life situation in poetry; students representing their understanding of some event of cultural significance in a unique and historically accurate narrative account, and so on). Indeed, nearly all students have a shot at producing what their teachers, peers, parents, and they themselves would consider to be novel and adaptive ideas, solutions, behaviors, and products. Research on this more everyday form of creativity has identified important cognitive strategies (e.g., divergent and evaluative thinking techniques) and environmental supports (e.g., creating engaging, intrinsically motivating environments) necessary for supporting students' creative potential.

The developmental perspective of creativity (which includes the various levels of creative magnitude) helps to dispel the myth that only certain people can be creative. At the same time, the developmental perspective acknowledges that although there will always be a few rare individuals (or groups) who have the capacity, environmental supports, and luck to attain creative eminence, the more everyday forms of creative expression are still important and attainable by almost anyone. For teachers, then, the goal becomes helping students to recognize and realize their creative potential within the various academic domains.

Theories of Creativity

Space limitations prevent a comprehensive review of creativity theories, but the trajectory of theoretical development can be characterized as moving from relatively focused, psychometric theories to multifaceted, relatively complex systems theories.

Psychometric Conceptions

The growth of creativity research in the second half of the 20th century was initiated by researchers studying creativity from a psychometric perspective. The work of J. P. Guilford and Paul Torrance was seminal in this regard. Guilford conceptualized creativity as a facet of his Structure of the Intellect model of human intelligence and developed a range of cognitive measures of creativity. Torrance, focusing more tightly on divergent thinking, developed the Torrance Tests of Creative Thinking, which remains one of the most popular creativity assessments and is used in several countries. Torrance's work popularized the conceptualization of divergent thinking in terms of fluency (total number of responses), flexibility (number of different kinds of responses), originality (the uniqueness and rarity of responses), and elaboration (the detail of responses).

Systems Theories

Starting in the 1980s—and mirroring theoretical developments in other fields—creativity researchers began to question the utility of psychometric conceptions of creativity. These scholars noted that creativity was a broad construct with multiple, diverse influences and outcomes (as opposed to the more narrow cognitive conceptions of the traditional psychometric

approach). This changing attitude resulted in part from the broadening of the field to include researchers with wide-ranging interests and backgrounds. The result was a flurry of systems theories of creativity from the late 1980s to the mid-1990s. Mihaly Csikszentmihalyi's systems theory, for example, emphasizes the interaction between an individual, the domain, and the field in which creativity occurs. The systems perspective, common in most systems theories, focuses on the confluence of events that occurs when creativity happens rather than considering creativity to be a trait of an individual. For example, most people do not understand Einstein's Theory of Relativity, but accept it as true because the gatekeepers in the field accept it. A domain is the cultural or symbolic portion relevant to creativity. Creativity "happens" when an individual changes a domain. Other popular and influential systems theories include Teresa Amabile's Social Psychology of Creativity, Robert Sternberg and Todd Lubart's Investment Theory of Creativity, and Mark Runco's Psychoeconomic Theory of Creativity, among others.

Types of Creativity Research

Scholars representing multiple disciplines (e.g., psychology, education, history, the arts, sociology, anthropology, and business) have contributed to the development of creativity theory, research, and practice. The upshot of this multidisciplinary effort has resulted in the broadening of the field and the emergence of multiple avenues and venues for creativity research. For instance, the broadening of the field is evinced in a steady stream of new creativity handbooks and edited volumes, the sustainability of multidisciplinary creativity research journals (e.g., *Creativity Research Journal, Journal of Creative Behavior*), and the emergence of new scholarly journals (e.g., *Journal of Thinking Skills and Creativity; Psychology of Aesthetics, Creativity, and the Arts*).

Several distinct approaches are used to examine creative phenomena, with a majority of research historically relying on *psychometric methods*—the direct measurement of creativity and its perceived correlates in individuals. Practically all current work on creativity is based upon methodologies that are psychometric or were developed in response to perceived weaknesses of creativity measurement. Work by Guilford and Torrance, which, as mentioned earlier, focused on cognitive assessment, formed the foundation for

psychometric approaches, and much of their work remains in wide use among creativity researchers. But psychometric methods have been extended to the study of attitudes, personality, motivation, and other noncognitive aspects of creativity. The advantages of psychometric approaches include the existence of a number of refined instruments, which promotes comparison of results across studies; disadvantages include the often narrow lens through which creativity is viewed and the lack of psychometric advances to match the considerable theoretical advances in recent decades.

The *experimental approach* is quite similar to the psychometric approach in that experimental researchers use many of the same instruments used by psychometricians to measure creativity. Perhaps the best known line of research in this area involves Amabile's studies of the impact of reward and evaluation conditions on creative production. Although experimental designs include added logistical and financial costs (as compared to nonexperimental designs), the advantages of the experimental approach include the confidence with which conclusions can be made about intervention effectiveness. Still, as some scholars have noted, because experimental designs require direct intervention and manipulation (as opposed to naturalistic observations and case studies), they may preclude the ability for documenting how creativity develops (more naturally) in a given sociocultural context.

The *historiometric approach* involves the analysis of quantitative data drawn almost exclusively from historical documentation. Although studies of eminence have relied on historiometric techniques at least as early as the 1950s, this empirical approach is best exemplified by the prolific works of Dean Keith Simonton, who has both created and refined the methodologies and used these techniques to study creativity exhaustively. Historiometric methods have been used to study the relationships between creativity and leadership, age, productivity, invention, and eminence, among many other areas. An advantage of this approach is the ability to consider creativity within its proper historical context, which proves to be difficult using other empirical approaches. On the downside, this approach relies almost exclusively on the study of Big-C Creativity, potentially limiting its application to everyday creativity.

The *biographical* or *case study approach* is similar to the historiometric approach in its focus on eminent creators and their work. However, the case study approach strongly favors qualitative research methodologies, with the attendant advantages regarding depth of analysis and limitations regarding generalizability. For both historiometricians and biographers, their focus on Big-C Creativity (i.e., indisputable instances of creativity) helps researchers avoid the problems and issues surrounding the definition of creativity faced by investigators adhering to most other methodological approaches. But again, applicability of results to everyday creativity may be an issue.

Although the use of *biometric methods* to study creativity, such as functional magnetic resonance imaging (fMRI), has significant potential, their application to the study of creativity has been highly limited. The ability to study brain function during creativity problem solving has clear advantages, but the use of fMRI in this context has been limited because of the high cost of such research, the infancy of the technology, and a lack of interest among neuropsychologists. As these issues change—and evidence suggests that this is happening—biometric approaches should become more common.

Although the various approaches to the study of creativity share many features, fundamental differences distinguish them from one another. The most significant differences involve the research designs commonly used, specific areas focused upon by researchers, and the time frame in which data are collected.

Major Empirical Themes

Two lines of inquiry are important for educators and educational psychologists to understand: the issue of domain specificity versus domain generality, and issues surrounding the enhancement of creativity.

Generality Versus Specificity

Whether creativity is domain general or domain specific is one of the hottest—yet most enduring—debates among creativity researchers. In essence, the debate boils down to whether people who are creatively productive in one domain are likely to be similarly productive in a different domain (or domains). Such distinctions are important because the generality position implies that general skills can be used to enhance creativity. But if creativity is domain specific, general creativity training would be highly

unlikely to promote transfer across domains and would, in effect, be pointless.

The specificity position, which is currently the dominant perspective, is supported by recent research on situated cognition and other areas within cognitive science. For instance, domain-specific creative tasks tend to have low correlations with each other, and task-specific training typically yields task-specific creative performance. However, other researchers argue that a domain-specific conception fails to account for theoretical and methodological issues. For example, a systems approach to creativity takes the view that creativity cannot be determined entirely within a domain. Implicit theories of creativity (i.e., layperson or folk definitions) also support a domain-general perspective.

A more fruitful question focuses on which aspects of creativity are domain or content general and which are domain or content specific, with the answer changing as a person develops and matures. As people age, they are forced to make choices, related to both their careers and their personal lives, that necessarily limit their ability to work productively in multiple, distinct domains. Some creative individuals do work in multiple domains, but they tend to be the rare exceptions that prove the rule. The implications of this perspective for practice are that some aspects are domain general, some are domain specific, and enhancement efforts should focus on helping individuals develop their creative abilities in whichever areas they choose—keeping in mind that some of the skills and attitudes will transfer to other domains and tasks.

Enhancement

Research on the effectiveness of efforts to enhance creativity is controversial, conflicting, and often disappointing. For example, many studies provide evidence of the ability of divergent thinking techniques to increase divergent thinking test scores, but these gains are often short-lived, and the skills prove difficult to apply to other contexts. Another example involves group problem solving. The work of Alex Osborn, Torrance, and many others suggests that groups generate more ideas than individuals working under otherwise similar conditions, and that group participants rate the creative performance more favorably than individuals working on similar problems. At the same time, many researchers have found that group problem-solving strategies, such as brainstorming, produce fewer and less original ideas than do individuals. The creativity enhancement literature is rife with such contradictions.

Several researchers have suggested possible reasons for the lack of clear effectiveness information regarding creativity enhancement: the lack of appreciably new enhancement strategies at the same time that our theoretical understanding of creativity has advanced exponentially; widely held misconceptions and myths about creativity (often created by an over-reliance on Big-C Creativity), which most "classic" enhancement efforts fail to address; negative effects of the numerous pop psychology and commercialized approaches (many of which are merely repackaged versions of early divergent thinking strategies); early work conducted in relative isolation from mainstream psychology; reliance on strategies and programs that assume a strong domain-general position; and conflicting or vaguely implied definitions of creativity. This last point is very important—if researchers studying creativity enhancement fail to define creativity or define it imprecisely, conflicting results should be expected.

Looking at creativity enhancement through the lens of the definition of creativity described earlier, a promising avenue for enhancing creativity is to optimize the time an individual spends in ideal aptitude-process-environment contexts. This may be similar to Csikszentmihalyi's concept of flow and Sternberg's emphasis on contextual awareness in his theories of intelligence. However, the ideal creative context needs to be identified for each individual. Not only will this vary across individuals, but across time, process, and environment as well. Many approaches to problem-based learning promote these principles, suggesting that related activities may be a fruitful avenue for future enhancement efforts.

Joseph Renzulli's Schoolwide Enrichment Model emphasizes many of these approaches and may be the most appropriate program for the enhancement of creativity. Initially designed as an education system for gifted students, Renzulli's approach has been described by some observers as a creativity enhancement model, and viewed from this perspective, it is considered to be quite successful. Renzulli has recently adapted the model to fit a variety of instructional contexts, and his work should be consulted by anyone considering large-scale enhancement efforts.

In the end, it is reasonable to conclude that a growing number of educational psychologists value creativity, would like to enhance it, and are confused

about how to proceed. Addressing complex phenomena such as creativity is never easy, and recent conceptual and empirical advances should illuminate the issues surrounding enhancement of creativity.

Creativity and Educational Psychology

Given that all students have creative potential and that creativity can help complement and extend learning within the various academic domains, there should be little doubt that creativity represents an important construct for educational psychologists. Although creativity has dwelled somewhat on the margins of educational psychology (particularly during the era in which behaviorism held sway over the field), the rise in constructivist views of learning has established a growing recognition that creativity and knowledge construction are complementary processes. This recognition is not entirely new, as many early progenitors of modern constructivist views of learning (including John Dewey, Jean Piaget, and Lev Vygotsky) made explicit references to the relationship between learning, creativity, imagination, and the development of robust understanding. What is new, however, is the wealth of knowledge both in the domain of educational psychology and in the interdisciplinary field of creativity studies.

For instance, educational psychologists have established important theories and empirically tested insights pertaining to student motivation, learning and development, assessment, the psychology of teaching, and contextual factors that mediate effective teaching and learning. Moreover, advances in research methods (both qualitative and quantitative) and advances in analytic techniques (e.g., everything from hierarchical linear modeling to more situated, interpretive analyses) position educational psychologists to make significant contributions to the study of creativity and its relationship to teaching and learning. Similarly, creativity researchers have engaged in parallel efforts in which they have examined the development and expression of creativity in educational contexts. For instance, creativity researchers have developed full programs of research (including the development of theoretical models and innovative analytic and assessment techniques) aimed at examining the motivational, cognitive, affective, and socio-environmental factors that mediate the fulfillment of students' creative potential. What is now needed is a well-articulated bridge between these parallel efforts, both to reduce unnecessary redundancies and to maximize the synergies between these related knowledge bases and lines of inquiry. Educational psychologists have a unique opportunity to bridge these complementary programs of research such that existing knowledge can be brought to bear on the advancement of what is known regarding the relationship between human learning and creative expression.

CRITERION-REFERENCED TESTING

Definition and Features

A criterion-referenced test (CRT) provides a measure of an individual's absolute performance or behavior on a well-defined domain. The domain may include

a set of learning/behavioral objectives to be mastered or a set of standards to be achieved. The history of CRTs dates back to a 1963 essay by Robert Glaser in which he introduced criterion referencing as a new type of approach to test development and interpretation. Glaser indicated that the absolute comparisons that formed the basis of CRTs were preferable to the relative comparisons made by the norm-referenced tests (NRTs) widely used at that time.

One way to gain a better understanding of exactly what a CRT entails is to compare it to an NRT. Within this section, CRTs are further defined and comparisons to NRTs are made. The next section discusses the development, use, and interpretation of CRTs in large-scale tests used for accountability purposes. It includes issues of alignment and validity, performance levels, and standard settings. The third section discusses the use of CRTs for classroom instructional purposes. The final section briefly describes guidelines available to assist test users in selecting and interpreting CRTs.

What Does a CRT Measure?

Whereas NRTs compare an individual's performance to the performance of others in a comparison group, such as all students in a state or across the nation, CRTs compare an individual's performance to standards or learning objectives. Because of this distinction, interpretations of NRTs are often referred to as relative comparisons and CRTs as absolute comparisons. In a CRT, test users are concerned about knowing whether the student has achieved a standard or mastered a learning objective. They are not concerned about the position or ranking of the student relative to other students.

What Is the Domain for a CRT?

CRTs consist of a well-defined domain of knowledge, skills, and/or behaviors to be measured. The domain for a CRT is narrower and more clearly delineated than the domain for an NRT, which is usually broader and covers many objectives. The level of specificity, however, varies somewhat across different types of CRTs. In some classroom situations, CRTs are called *objective-referenced* because they measure detailed learning outcomes (e.g., adding two three-digit numbers that require carrying). In large-scale tests that are standards-based, the criteria may be slightly less detailed (e.g., measuring whether a student can represent mathematical situations using algebraic symbols).

How Are the Items Designed?

In NRTs, items are usually developed so that the difficulty level is average and discrimination among student scores is high. Because easy items do not lend themselves to discriminating among individuals, they are not usually used on NRTs. However, for CRTs, the item difficulty or discrimination is not of utmost importance. Rather, the most critical aspect of developing a CRT is that each item must have a direct match to a learning objective, behavior, or standard within the domain. Depending on the purpose of administering the CRT, the items may be very easy or difficult. When a test is given immediately after instruction to determine whether students attained the knowledge necessary to move on to the next topic, it is likely that the items will have a low difficulty level. Also, there would be no concern about whether the test was able to discriminate among students.

What Types of Scores Do CRTs Produce?

Unlike NRTs, which provide standard scores and percentiles to describe a student's placement or ranking within a comparison group, CRTs provide percentages that indicate whether a student has achieved mastery or proficiency regardless of the performance of other students. CRTs may indicate (a) the number or percentage of items that were answered correctly by each individual, (b) the speed of performing a certain task (e.g., typing on a keyboard), (c) the precision of performance (e.g., measuring an object to the nearest millimeter), or (d) the quality of a behavior (e.g., tying a shoe). Interpretations from these scores help to determine whether a student has achieved mastery on a set of skills, tasks, or behaviors. Other CRTs, such as those that are standards-based, combine a student's performance on a set of items and categorize him or her into one of several performance or achievement levels. The student might be classified as being basic, proficient, or advanced with regard to a standard in a subject area. Results may also be aggregated across all students in a school, grade, or subgroup (e.g., ethnicity, gender) so that teachers and administrators can examine the percentage of students classified within each level.

What Are the Purposes for Using CRTs?

CRTs can be used for several purposes. It is the responsibility of the test user to determine whether the test design, item design, and type of scores match the intended use and interpretation of the test. One set of purposes for using a CRT is to determine whether individual students have mastered the learning objectives, acquired the skills necessary for placement into a particular program, or demonstrated the ability to perform essential behavioral tasks. In these situations, reporting meaningful score interpretations to parents is of extreme importance because it directly relates to their child's success. Another purpose of a CRT is to inform classroom instruction and ensure that adequate learning experiences are being provided to students. Teachers can identify students' strengths and weaknesses and modify instruction to address these areas.

CRTs may also be used in program evaluation. They provide answers to questions such as, "How effective is a new instructional program in our school?" "What impact does the program have on our students?" and "Is it worthwhile to continue the program?" This information is valuable to teachers and administrators as they judge the effectiveness of a program or curriculum in their school. Finally, another use of CRTs in recent years is to hold schools accountable for student learning. Within this era of No Child Left Behind (NCLB), state testing programs are using large-scale CRTs to determine whether students are achieving standards for reading, mathematics, and science. Although the media often rank schools in terms of student performance, it is not helpful for a school to know only that they are performing better or worse than other schools. For accountability purposes, the school needs to know the percentage of students achieving the state standards so they can work toward having every student perform at least at the proficient level. The following section contains more information on large-scale CRTs.

Large-Scale Criterion-Referenced Testing

In the 1990s, there was a movement by states to develop academic content standards and create state-level criterion-referenced assessments to measure student performance against those standards. Many assessments included performance-based tasks, and a few states, such as Maryland, had tests that were entirely performance based. When the No Child Left Behind legislation was enacted, it became necessary for all states to have an assessment system that would identify whether students were proficient. One of the major goals of NCLB is that all students will be proficient in reading and mathematics within a period of 12 years.

Because of NCLB, some states had to change their assessment systems, especially those with tests that were completely performance based. Maryland's test, for instance, provided school and grade-level results but not individual student scores, which are necessary for NCLB. In order to provide student scores, the number of items on which each student tests must be large enough to ensure a stable estimate of his or her performance. Therefore, Maryland had to abandon its performance-based assessment and instead use one that incorporated additional items that were not performance based. Many other states created new assessments; modified their existing assessment; or reverted back to using an off-the-shelf, commercially published criterion-referenced test. The latter is somewhat undesirable because the test may not provide an exact match to the state standards. However, test publishers are now beginning to collaborate with state representatives to produce custom-designed tests that will meet their specific needs.

Alignment and Validity

One of the major features of a well-designed CRT is that the test items are directly matched to a specific domain, standard, or learning objective. Large-scale CRTs used for accountability purposes are considered to have high stakes. For this reason, it is imperative that there exists a high degree of alignment among all aspects of the assessment system—state standards, test items, curriculum taught in school district, and instruction in teachers' classrooms. If any of these aspects is not in alignment, then the validity of the interpretations made from the CRT results is suspect.

Several models are available to examine alignment between state standards and tests. The models vary in their complexity. Low-level models involve experts examining the content of each test item and determining the degree to which it is related to the content in the standard. Models at the next level have additional criteria for determining the match between items and standards, such as the cognitive complexity of the item. The most complex alignment models examine several interrelated dimensions, including content, depth, emphasis, performance, and accessibility.

Even when there is a high degree of alignment between standards and test items, if there is not a match between the test and classroom instruction, then the assessment system will not be valid. Students must be given an opportunity to learn the content and processes specified in the standards. If they do not have this exposure in the classroom, they cannot be expected to demonstrate what they know and can do. Moreover, the conditions under which they solve problems should be the same in the testing situation as in the classroom; for instance, the accessibility of manipulatives and calculators in math. Various approaches have been described by educational researchers to examine the match between the test and classroom instruction. Some approaches collect evidence from questionnaires and interviews with teachers and principals. Teachers rate the similarity between the content and processes they teach in the classroom to the specific state standards. These self-report data also gather information on the unintended or potentially negative consequences of the assessment system, which is another important type of validity to be examined for CRTs. A more direct technique for gathering evidence of alignment is through classroom observations or the collection of sample instruction and assessment materials used by teachers. Classroom materials can be evaluated using a coding scheme that focuses on the content, level of cognitive complexity, and item response types, and comparing these to the test items.

Performance Levels

One way that standards-based CRTs report scores is in terms of a small number of performance levels. The number of levels is typically between three and five. The Pennsylvania System of School Assessment (PSSA) uses four performance levels: below basic (inadequate academic performance), basic (marginal), proficient (satisfactory), and advanced (superior). For the purposes of NCLB, each student is classified into one of the levels for each subject area assessed—reading and mathematics. For the purposes of disseminating test results to other stakeholders, Pennsylvania produces individual student reports for parents and school summary reports for schools and districts.

An individual student report for PSSA math identifies the performance level that the student achieved when aggregating results across items on the math assessment. Most items are multiple choice and assess a variety of skills from recall to problem solving.

A small set of open-ended items is included to measure students' problem-solving and reasoning skills and to require them to explain answers, describe solution strategies, create graphs, and so on. The individual student report also provides results for each academic standard. For the 2005 PSSA, there were five major reporting categories in math: numbers and operations, measurement, geometry, algebraic concepts, and data analysis. They are aligned to the content standards used by the National Council of Teachers of Mathematics. For each category, the number of points achieved by the student is shown in comparison to the total number of points possible. As an example, a student might receive 12 out of 14 possible points for the geometry standard that assesses knowledge of shapes, properties of shapes, and use of geometric principles to solve problems. This detailed information helps parents identify their child's strengths or weaknesses in math.

A school summary report for mathematics shows the number of students taking the assessment and the percentage of students in every grade level scoring at each of the four performance levels. With respect to individual standards on the assessment, the report lists the number and percentage of total points achieved by all students in a grade level. This allows teachers and school administrators to interpret results for the purposes of examining the math curriculum and planning instructional improvements.

It should be noted that even though the PSSA is a criterion-referenced test, the individual report and school summary reports also provide norm-referenced interpretations of results. The individual report presents average state-level scaled scores, gives a percentile to show the percentage of students across the state that performed at the student's scaled score or lower, and charts the difference between the student's points achieved on each standard compared to the state average points achieved. Similar norm-referenced interpretations are made in the school summary report. As Robert Linn and Norman Gronlund indicated in their book, *Measurement and Assessment in Teaching*, the distinction between large-scale CRTs and NRTs is becoming less clear-cut. A dual interpretation of tests is now on the increase.

Standard Setting

A natural question that follows a discussion of performance levels is about the criteria used to place

a student into a level. Usually, cut scores between levels are established. The process of creating the cut scores is called standard setting. There are many different methods of standard setting, all of which require making judgments. It is for this reason that some people have questioned the validity of performance levels, saying that it is difficult to get judges to agree on the cut scores, and thus they are inherently arbitrary. However, others believe that consistency among judges can be obtained through rigorous training and the use of previous test score data. Recent research is focusing on comparisons of standard-setting methods and their validity.

The Bookmark standard-setting method is widely used in kindergarten through twelfth-grade settings. The PSSA cut scores are based on a modification of this method. Judges, who were educators across the state, were given detailed written descriptions of each performance level and a booklet of all items on the assessment ordered from the easiest to most difficult based on previous students' responses. The judges were asked to think about a student who would be at the borderline between two levels (e.g., below basic and basic) and assess whether the student had a high probability of answering the item correctly. Each judge recorded his or her decision. Discussions occurred after each round, and the process was conducted repeatedly. After the judges' final recommendations were received, student scores were converted to scaled scores that identified a range for each level. For example, in 2005, a fifth-grade student with a scaled mathematics score between 1312 and 1482 would be categorized as proficient in math. A fifth-grade student with a scaled math score equal to or above 1483 would be advanced.

CRTs Used in Classroom Instruction

In Anthony Nitko's 2004 book, *Educational Assessment of Students*, he describes three types of referencing frameworks used to interpret achievement: norm-referencing, criterion-referencing, and self-referencing. Each of them contains a different perspective on achievement while increasing the meaningfulness of test results. A norm-referencing framework is not usually the most useful in making instructional decisions in the classroom or informing parents. When parents know only that their child is better at math than other students, they are left wondering about the kinds of math problems their child can solve successfully.

When you want to identify specific learning objectives that are achieved by each child, a criterion-referenced framework is most appropriate. Teachers can uncover math processes that are difficult for students (e.g., transforming numerical data to a visual display), and they can identify specific misconceptions students may have (e.g., about interpreting a line graph showing the relationship between speed and time). Teachers can learn about students' thinking and reasoning on complex math problems, and they can gauge their students' ability to communicate mathematically. All of this knowledge that the teacher learns about students becomes useful in planning and modifying instruction for all students. The teacher may decide to reteach, review, or proceed ahead with a new topic. Knowledge gained about individual students' deficiencies can also aid the teacher in individualizing instruction, giving each student additional learning opportunities or resources that address his or her specific needs.

A criterion-referencing framework provides summative and formative feedback. The previous paragraph gave examples of evaluating students for formative purposes in order to continually improve the teaching and learning process. The framework also allows for summative evaluations that inform teachers and parents about the level of achievement at which students are performing in relation to the absolute learning objectives. It is possible that all or most of the students in a class achieved mastery or are classified at the highest performance level. In this case, the items on the CRT would be considered "easy" for students, which is acceptable if the test was intended to measure knowledge necessary for proceeding with further instruction. It is also possible that all or most students do not achieve mastery or are not classified as proficient. Several reasons might explain this outcome. The learning objectives in the classroom may not be aligned with the items on the assessment, or the objectives may not be placed appropriately in the curriculum. Another reason may be that students did not have an opportunity to learn the skills and knowledge because the instructional methods and techniques used by the teacher were not effective. Teachers can reflect on these possibilities and modify accordingly.

Before leaving this section, a brief mention is made about the third type of referencing framework identified by Nitko because it serves to illustrate what a criterion-referencing framework is *not*. A self-referencing framework is based on the teacher's perceptions of a student's capacity to perform well in

a content area. Students would receive a high grade if they are achieving at or above the level at which they are perceived to be capable. Likewise, the reverse would be true, that is, students would receive low grades if they are achieving below the level at which they are capable. A student may also receive a high grade if he or she began the learning process with little or no prior knowledge and then made some improvement. As would be expected, there are pros and cons to this framework. Proponents believe that it can help increase student motivation and reduce competition among students. Those not in favor say that teachers' perceptions of students' capabilities are subjective and also that the framework leads to a grading procedure based on effort alone. Furthermore, it may produce a ceiling effect for those students who come to class with a great deal of prior knowledge.

Criterion-Referenced Letter Grades

There are several ways to assign a grade based on a variety of evaluation components. Nitko describes several methods, three of which are summarized here. One method involves using a fixed percentage. First, the number of points earned on each evaluation component used in the classroom is converted to a percentage. The percentages are then transformed to letter grades. The teacher defines a range of percentages for each letter grade. The ranges are equivalent across components.

The total points method first produces the total number of points a student achieved on all of the evaluation components. The number of points achieved is compared to the maximum number of points available across all components. Ranges of maximum points are defined for each letter grade. In this method, the number of points assigned to each component determines the weight, or worth, of each component. For example, a project might be assigned 50 points, whereas a short quiz might be assigned 10 points. The third method is called the quality level method. It is similar to using a rubric for scoring student responses on a performance task. The quality of student performance necessary to achieve each level is thoroughly described. Teachers match the quality of student work to the appropriate letter grade.

Guidelines for Appropriate Selection and Use of CRTs

This final section describes two external sources that serve as guides for educators and psychologists who develop, select, and use assessments. One source is called the *Standards for Educational and Psychological Testing.* The most recent version was developed in 1999 through a joint effort by the American Educational Research Association, the American Psychological Association, and the National Council on Measurement in Education. The document identifies standards that are designed to evaluate educational and psychological tests. These widely accepted standards and criteria provide information to test developers, users, and takers on the entire testing process. The document is organized into three parts: (1) test construction, evaluation, and documentation; (2) fairness in testing; and (3) testing applications.

Another source is the *Code of Fair Testing Practices*, published by the national Joint Committee on Testing Practices in 2004. The Code applies to all educational assessments regardless of their referencing framework (CRTs or NRTs) or the mode in which they are administered (computer-based, paper-pencil, or performance). The overall purpose is to ensure that tests are fair to all test takers regardless of their demographics (e.g., ethnicity, gender, age) in terms of a variety of aspects, including the standardization of administration conditions, preparation for the test, knowledge about the test's content and purpose, accurate reporting of results, and appropriate interpretation of the results.

The Code was designed to represent selected portions of the *Standards for Educational and Psychological Testing* by making the information relevant and meaningful to states, districts, schools, organizations, and individuals. Even though the Code is specifically written for professionally developed tests, the guidelines can also be used by teachers to inform and improve the fairness of their classroom assessments. The Code is organized according to four areas: (1) developing and selecting appropriate tests, (2) administering and scoring tests, (3) reporting and interpreting results, and (4) informing test takers. In each area, guidelines are given for both test developers and test users. Examples of guidelines in the third area are that test users should always take into account the nature of the content assessed when making meaning of test results, ensure that the test is used for its intended purposes, gain knowledge of the type of scores reported (e.g., method for establishing cut scores for mastery or performance levels), and understand that one test score should not be used as the sole determinant in making a decision about a student.

CROSS-SECTIONAL RESEARCH

Research is commonly designed to test causal hypotheses. Whether the hypothesis is general or specific, it can be expressed as "IV causes DV," where IV is an independent (causal) variable and DV is the dependent (consequent) variable. There are three generally accepted conditions for establishing causality— *temporal ordering*, *reliable covariation*, and *nonspuriousness*. These conditions can be met in either longitudinal or cross-sectional studies, but there is an important difference between the two. Longitudinal studies compare two or more time periods on a set of cases. The resulting regression coefficient describes the amount of *change* in the DV resulting from a unit change in the IV. Cross-sectional studies compare a set of individuals (persons or groups) who differ on the DV. The resulting regression coefficient describes the amount of *difference* between individuals on the DV, given a unit difference in the IV. Longitudinal and cross-sectional designs will yield the same regression coefficients only if the process generating variation in the DV is constant across individuals and stable across time periods.

Temporal Ordering

Although the term *cross-sectional* would seem to imply that the variables in the hypothesis are measured at exactly the same time, this is not always the case. Frequently, a study is considered cross-sectional as long as none of the variables is measured at two or more points in time—which would make the analysis *longitudinal.* For example, prediction of college freshman grade point average (GPA) from Scholastic Aptitude Test (SAT) scores would be considered cross-sectional even if SAT scores were taken 18 months before the GPAs.

Reliable Covariation

Establishing reliable covariation requires three conditions—a measure of association between two variables, statistical significance, and sample representativeness.

Measures of Association

There are many measures of association between pairs of variables ("bivariate correlation") that depend on the ways in which the variables are measured. The most widely recognized, the Pearson product-moment correlation coefficient (r), is used when both variables are continuous (either interval or ratio). Other correlation coefficients arise when the IV and DV are other types of scales (e.g., the phi coefficient is used when both variables are dichotomies) or combinations of scales (e.g., the point-biserial correlation is used when one variable is continuous and the other is a dichotomy). However, the textbook formulas for these coefficients are simply special cases of the Pearson r.

One important consideration in estimating the degree of association between two variables is whether the obtained correlation coefficient has been attenuated by unreliability in the variables or diminished by variance restriction. The maximum observed correlation

between X_1 and Y is limited by the reliabilities of the two variables. Thus, it is extremely important to measure variables as reliably as possible. This can be achieved by rationally constructing multi-item scales for both variables, pretesting these scales, conducting item analyses to refine the scales, and reporting the scales' reliability coefficients (e.g., Cronbach's α) in the study results. Variance restriction occurs when a floor or ceiling effect produces a skewed distribution of very low or very high scores, respectively. A very high proportion of low scores results when using an ability test that is too difficult or an attitude inventory whose items are too unpopular. By contrast, a very high proportion of high scores results from using an ability test that is too easy or an attitude inventory whose items are too popular.

Statistical Significance

The need to establish statistical significance arises when data are collected by drawing a sample of cases from a larger population. In such cases, the degree of association measured by the sample statistic r might differ from the corresponding degree of association measured by the population parameter ρ. The average difference between r and ρ decreases as the size of the sample increases, and procedures for statistical significance testing are used to calculate confidence intervals for the population value.

As a practical matter, sample size is important because the *statistical power* of a research design—the probability of correctly detecting a statistically significant relationship that truly exists in the population—decreases as the sample size decreases. Specification of a Type I error rate (α), desired statistical power (π), and an expected population correlation coefficient (ρ) make it possible to determine the sample size (n) needed for a given study. It is important to recognize that the resulting n is the number of respondents who provide enough data to calculate the correlation coefficient(s). As noted in the discussion of sampling below, this number must be adjusted for nonrespondents and incomplete data. That is, the sample size must be 500 if 250 are needed and there is likely to be only a 50% response rate.

Moreover, survey researchers typically find that respondents answer some items but not others. In some cases, the proportion of respondents who answer all items can be as low as 20%, so *listwise deletion* (removing all respondents with incomplete data) can severely deplete an already small sample size even though it yields reasonable estimates of standard errors for regression coefficients, b_{Yi}. On the other hand, *pairwise deletion* (computing the correlation between each pair of variables using only the cases responding to those variables) yields larger samples but can produce correlation matrixes that do not meet the mathematical requirements for multiple regression analysis (i.e., they have negative determinants and an undefined n to use in estimates of standard errors). *Unconditional mean imputation* (replacing missing values on a variable with the mean across all cases for that variable) avoids some of these problems but produces biased estimates of variances and covariances. *Conditional mean imputation* (regressing the available cases for one IV onto the remaining IVs and then using the resulting regression coefficients to estimate the missing values) is better than pairwise deletion and unconditional mean imputation but still underestimates the standard errors of the b_{Yi}. However, *maximum likelihood* and *multiple imputation* methods are likely to produce reasonably good estimates of the b_{Yi}, standard errors, and test statistics if data are *missing completely at random* (*MCAR*, the absence of data on Y is unrelated to Y or to any of the X_i), or *missing at random* (*MAR*, the absence of data on Y is unrelated to Y after controlling for the X_i). Data that are *not missing at random* (*NMAR*, there is a systematic structure to the absence of data) require even more sophisticated methods.

Sample size also is important as it relates to the number of IVs used in a regression analysis. Tests of significance for regression coefficients have only $n - k - 1$ degrees of freedom (where k is the number of IVs). Thus, as k approaches n, the estimated standard errors of the regression coefficients become increasingly large and the multiple correlation (*Multiple R*) of the IVs with the DV approaches 1.0. This problem, known as *overfitting*, will be obvious when $n/k = 1$ because $R = 1.0$ is absurd. However, overfitting will still be present, but difficult to detect, when n/k is only slightly larger than 1. Researchers are well advised to generate a sample sufficiently large that $n/k > 5$. It is also advisable to correct for *shrinkage* by reporting an *adjusted R*, which compensates for the number of predictors (see Equation 1). Alternatively, one can *cross-validate* by applying the weights estimated from one subset of the data (the estimation sample) to predict scores in another subset (the holdout sample).

$$R^2 = 1 - (1 - R^2)\frac{n-1}{n-k-1} \qquad (1)$$

Sample Representativeness

The need for sample representativeness arises from a desire to avoid distortions in the estimates of population parameters. Sample representativeness is usually sought as a way to ensure that the sample estimate of a mean (M) or proportion (p) is unbiased. A sample can be assumed to be representative if it is randomly selected from the population of interest and there is a 100% response rate. *Random selection* means that every member of the population of interest has an equal probability of being included. This is relatively easy to accomplish if an adequate *sample frame* exhaustively lists all members of the population. For example, a roster of all students currently enrolled within a given school would be an adequate sample frame if a researcher intended to generalize the results of the study only to that school. It would not be an adequate sample frame if the study results were also intended to be generalized to students in other schools or to students who might be enrolled in future years.

These more complex situations may require more sophisticated strategies for sampling a much broader population (all students in a school district, state, or the entire country). For example, stratified sampling divides all sample elements, usually individuals, into strata (categories) based upon their known attributes so that each element is in one and only one stratum. Then, a random sample is drawn from each stratum. *Proportionate stratified* sampling selects elements so that the proportion of each stratum in the sample is the same as its proportion in the population. This strategy is useful in ensuring that relatively rarely occurring sample elements (e.g., households of Native American ancestry) are represented in the sample. In some cases, researchers want to compare these strata on other variables, such as their average income, but proportionate stratified sampling would not provide an adequate sample size for the infrequent strata. *Nonproportionate stratified* sampling solves this problem by oversampling the infrequent strata—selecting a higher proportion of sampling elements from those strata than their proportion in the population. *Cluster sampling* is used when there is no sample frame from which to select a sample, so elements are selected in groups. For example, a researcher might randomly select five states from the entire country, then five counties within each of those five states, a single high school from each county, and a simple random sample of students from each high school. Cluster sampling makes it possible to draw

a nationally representative sample, but its sampling errors are greater than those for simple random sampling because the elements within a cluster are more similar than randomly selected elements from the population. This error decreases as the number of clusters increases (but, of course, increasing the number of clusters increases survey costs) and as the homogeneity of cases in each cluster increases. Although superficially similar, stratified sampling differs from cluster sampling in that a stratified sample of, for example, counties within a state would further select elements from all strata, whereas a cluster sample would further select elements only from the selected clusters.

A 100% response rate is quite rare, even in highly controlled settings such as schools and other organizations. However, there are many procedures for ensuring a high response rate. In-person interviews generally have higher response rates than telephone interviews, which, in turn, generally have higher response rates than mail questionnaires. Unfortunately, response rates for all data collection procedures have been declining significantly in recent years. In mail surveys, it is extremely helpful to keep the questionnaire short (approximately two to three pages printed in booklet form). It also helps to send a pre-letter, the initial questionnaire, a reminder postcard, and two replacement questionnaires at approximately 2-week intervals.

Because random selection and 100% response rarely occur, it is common to collect data on the demographic characteristics of the respondents and compare these to the characteristics of the population. This is feasible for general public surveys within political jurisdictions because census data on demographic characteristics such as gender, age, education, ethnicity, and income can be used to characterize the population. Although this strategy can assess the representativeness of the respondents with respect to the measured demographic characteristics, it cannot ensure that the respondents are representative with respect to any other variables. Thus, if the variables of interest (achievement motivation or fatalism, for example) are minimally related to the available demographic characteristics, it will not be possible to determine if the respondents are representative of the population with respect to the variables of interest. In sum, representativeness of the respondents with respect to the measured demographic characteristics can increase the researcher's confidence that the sample is representative with respect to the variables of interest, but cannot provide complete assurance that this is the case.

As it turns out, the issue of sample representativeness is less of an issue than it might appear. Recent research suggests that well-executed samples using Dillman's procedures tend to have respondents missing randomly rather than systematically. It is also important to recognize a critical distinction between applications such as public opinion polling and tests of causal hypotheses. The former usually report means or proportions, whereas the latter involve estimates of association (or equivalently, difference between means). Sample bias is much more likely to affect means and proportions than measures of association because the latter are mostly affected if sample bias produces a sample variance that is systematically different from that of the population. As noted above, the sample variance can be systematically restricted by a ceiling or floor effect, and this will cause downward bias in any estimated correlations. Alternatively, the sample variance can be systematically inflated if extreme groups have been selected, and this will cause upward bias in any estimated correlations.

However, there are cases in which explicit selection eliminates data on cases below (or above) a deterministic threshold. In other cases, incidental selection tends to eliminate only the highest or lowest cases. Such selection might occur on either the IVs or DVs. There are some models for analyzing *censored* samples, which have data on the IVs but not the DV. There are fewer models for analyzing *truncated* samples, in which both IVs and DVs are missing.

Nonspuriousness

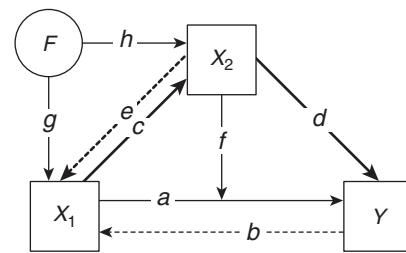
A relationship can be considered spurious if the true relationship between two variables has been obscured by another variable. As the discussion of unreliability and variance restriction indicates, it is also possible for a correlation to be spuriously low. However, the most common concern in causal analysis is that the degree of association between a hypothesized causal variable (X_1) and its consequent (Y) is spuriously high. The principal ways in which an apparent causal relationship can prove to be spurious are often described as *plausible rival hypotheses.* These are illustrated in Figure 1, which presumes that a statistically significant correlation exists between X_1 and Y that is caused by the hypothesized relationship, X_1 causes Y. If this hypothesis is true, the correlation between X_1 and Y is generated by the regression of Y


Figure 1   Basic Path Diagram

onto X_1. This is represented by path a, whose regression coefficient is b_{Y1}.

The first rival hypothesis is *reverse causation*, in which Y causes X_1. In this case, the correlation between X_1 and Y is due to path b, which is estimated by the regression of X_1 onto Y, b_{1Y}. The reverse causation hypothesis is ruled out if X_1 occurred before Y.

The second rival hypothesis is *reciprocal causation*, in which X_1 causes Y and Y causes X_1. In this case, the correlation between X_1 and Y is due to a combination of paths a and b. That is, both b_{Y1} and b_{1Y} are statistically significant. This model is usually tested using longitudinal data, but it can be tested with cross-sectional data under some conditions by using structural equation models.

The remaining rival hypotheses can best be understood by referring to Equation 2, which shows that the standardized regression coefficient for X_1 (b_{Y1}) is the same as r_{1Y} only if $r_{12} = 0$ or $r_{2Y} = 0$ (or both). Conversely, if r_{1Y} and $r_{12} \neq 0$, there is a possibility that r_{1Y} is spurious. This leads to four specific rival hypotheses.

$$b_{Yi} = \frac{r_{Yi} - r_{Yj}r_{ij}}{\sqrt{(1 - r_{ij}^2)}} \qquad (2)$$

The third rival hypothesis is *complete mediation*, in which X_1 causes X_2 and X_2 causes Y. In this case, r_{1Y} is due to paths c and d. That is, both b_{21} and b_{Y2} are statistically significant, but b_{Y1} is not. This hypothesis can be tested by regressing Y onto X_1 and X_2. If X_2 completely mediates the relationship between X_1 and Y (that is, X_2 is the direct cause of Y), b_{Y2} is statistically significant and b_{Y1} is not. Of course, b_{21} must also be statistically significant to establish mediation. If not, X_2 is an independent cause of Y that, according to Equation 2, cannot distort r_{1Y}.

A special case of complete mediation is *partial mediation*, in which X_1 has a direct effect on Y, as well as an indirect effect in which X_1 causes X_2, and, in turn, X_2 causes Y. In this case, r_{1Y} is due to paths a, c, and d. That is, b_{21}, b_{Y2}, and b_{Y1} are statistically significant. As is the case with complete mediation, a partial mediation hypothesis is also tested by regressing Y onto X_1 and X_2. Unlike the case of complete mediation, b_{Y2} and b_{Y1} are statistically significant.

The fourth rival hypothesis is *joint causation by a third variable*, in which X_2 causes both X_1 and Y. In this case, r_{1Y} is due to paths d and e. That is, b_{12} and b_{Y2} are statistically significant, but b_{Y1} is not. This hypothesis is identical to the complete mediation hypothesis except that X_2 causes X_1 rather than the reverse. Consequently, joint causation is tested in the same way as complete mediation. Joint causation can be distinguished from complete mediation if X_2 temporally precedes X_1.

A special case of joint causation is *partial causation by a third variable*, in which X_2 causes both X_1 and Y, but X_1 also causes Y. In this case, r_{1Y} is due to paths a, d, and e, so b_{12}, b_{Y2}, and b_{Y1} are statistically significant. This hypothesis is identical to partial mediation except that X_2 causes X_1 rather than the reverse. Consequently, partial causation is tested in the same way as partial mediation. As is the case with joint causation, partial causation by a third variable is distinguished from partial mediation if X_2 temporally precedes X_1.

The fifth rival hypothesis is *complete moderation*, which occurs if the regression of Y onto X_1 depends on the value of X_2. In this case, r_{1Y} depends on paths a and f. That is, $b_{(12)}$, where the subscript (12) denotes the product of X_1 and X_2, is statistically significant but b_{Y1} and b_{Y2} are not. This hypothesis is tested by regressing Y onto X_1, X_2, and X_1X_2 (the product of X_1 and X_2). If X_2 completely moderates the relationship between X_1 and Y, $b_{(12)}$ is statistically significant but b_{Y1} and b_{Y2} are not.

A special case of complete moderation is *partial moderation*, which occurs if the relationship between X_1 and Y is both multiplicative and additive. In this case, r_{1Y} depends on paths a, d, and f. This hypothesis can be tested in the same way as complete moderation. If X_2 partially moderates the relationship between X_1 and Y, $b_{(12)}$, b_{Y1}, and b_{Y2} are all significant.

The last rival hypothesis is that X_1 and X_2 are indicators of a single underlying factor F, so r_{12} is generated by the paths marked g and h. If this is the case, X_1 and X_2 can be combined by standardizing them

[i.e., $x_i = (X_i - M_i)/SD_i$, where M_i is a variable's mean and SD_i is its standard deviation] and then adding the standardized values (i.e., $F = x_1 + x_2$) to form an equal weighted composite. This hypothesis tested by regressing Y onto F and comparing the *multiple* R^2 of the equal weighted composite (which forces $b_{Y1} = b_{Y2}$) to the *Multiple* R^2 of the independent effects model regressing Y onto X_1 and X_2 (which allows b_{Y1} and b_{Y2} to differ).

Tests of the plausible rival hypotheses require that a measured third variable, X_2, be analyzed in order to estimate its influence. In some cases, there might be suspicion that an unmeasured third variable has influenced the observed correlation between X_1 and Y. In particular, some researchers have proposed that variables collected from the same source at the same time are contaminated by *common method variance* (CMV). The effects of CMV can be estimated using structural equation models or by using a theoretically unrelated variable that is likely to be contaminated by CMV but theoretically unrelated to any of the X_i or Y.

Aggregation

Researchers must recognize the distinction between the units of observation and the units of analysis. The *unit of observation* is the type of entity from which the data are collected; in most social and behavioral research, the unit of observation is the individual. The *unit of analysis* is the type of entity at which the measures are calculated and analyzed; sometimes, this is the individual, but other times, it is the group.

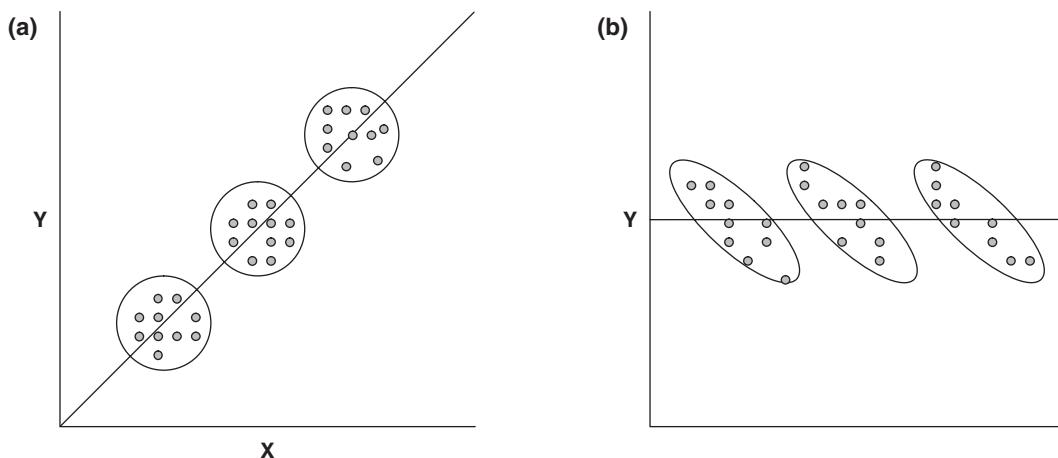
It is essential to be clear about the unit of analysis because that is the unit at which causal inferences must be made. It is an ecological fallacy to analyze data at the group level and draw inferences about individuals, whereas it is a reductionist fallacy to analyze data at the individual level and draw inferences about groups. Figure 2 shows how the direction of effect can be completely reversed when the proper unit of analysis is not recognized. Panel *a* shows zero correlations between X and Y when calculated at the individual level, as represented by scatterplots of the data that take the form of circles. However, systematic differences between the groups on both of the variables produce a positive correlation at the aggregate level. Conversely, Panel *b* shows negative correlations between X and Y when calculated at the individual level, as represented by scatterplots of the data that take the form of negatively sloped ellipses. However, systematic differences between the


Figure 2   Aggregation Biases

groups on X, but not Y, produce zero correlation at the aggregate level.

Resolution of the disparity between results at the individual and group levels depends on which is the logical unit of analysis for the researcher's theoretical perspective. When the unit of analysis is the group, researchers often use the group mean as the score for the group. However, it will often prove useful to analyze the group's dispersion (e.g., variance) as well. To examine both individual and group processes concurrently, researchers should use hierarchical linear modeling.

Common Research Designs

The discussion to this point has assumed that all relevant variables (i.e., all variables having significant causal effects on Y) have been measured. However, this is not always the case. Indeed, common research designs are defined by the ways in which the relevant variables are treated. In addition to being measured, they can be manipulated, controlled (held constant), randomized, or omitted.

Measured variables typically involve the collection of reports made by the respondents themselves or by external observers. Such measures typically include biographical data; cognitive, psychomotor, and physical tests; personality inventories and attitude scales; and assessments of social interaction. *Manipulated variables* involve differential treatment of research participants, as when one group of students is given

an advance organizer and another is not. *Controlled variables* are held constant, as when all participants in an experiment have been selected to have the same personal characteristics (e.g., age, gender, education) or to experience the same environmental conditions (e.g., light, heat, noise, and time pressure). *Randomized variables* are ones whose effect has been probabilistically neutralized by randomly assigning participants to conditions. Random assignment makes it statistically improbable that any unmeasured characteristics of the participants are correlated with the experimental treatments. *Omitted variables* are, as the name suggests, excluded from the analysis by failing to measure, manipulate, control, or randomize them. As a practical matter, every study must omit many variables because it would be impractical to measure, manipulate, control, or randomize all of them. Thus, theory is essential in determining which variables can be omitted safely in a given study because their absence is unlikely to bias the study's conclusions. In practice, this means researchers should carefully examine the previous research to identify relevant variables and be prepared to explain which ones can be safely omitted. This means being able to document that any omitted variables that are correlated with the DV are not also correlated with the IVs (these are independent causes that will not bias the estimates of the included variables). In addition, any omitted variables that are correlated with the IVs are not also correlated with the DV (these are not the DV's other causes).

This typology of measured, manipulated, controlled, and randomized variables leads to the three principal types of cross-sectional research designs—experimental, quasi-experimental, and nonexperimental. Experimental designs have at least one DV that is measured (the presence of multiple DVs does not make the design longitudinal unless these are repeated measurements over time), and the DV need not be continuous because there are analytic procedures for analyzing dichotomous DVs. At least one IV is manipulated, and participants' assignment to treatment is randomized. Many of the other variables (respondent characteristics such as age and gender or environmental characteristics such as light and noise) are controlled in laboratory experiments, but they must be ignored in field experiments. Experimental designs usually produce the strongest causal inferences, but it is possible for a confounded design to simultaneously manipulate two distinct variables in a way that does not allow any effect to be attributed unambiguously to either variable. Experimental designs are sometimes strengthened by measuring relevant causal variables that are not controlled or part of the treatment. These measured variables are incorporated into an analysis of covariance.

Quasi-experimental designs, like experimental designs, have at least one DV that is measured and at least one IV that is manipulated. However, participants' assignment to treatment is *not* randomized. In many cases, the "manipulated treatment" in a quasi-experimental design is a naturally occurring difference between intact groups. Thus, any apparent difference associated with the treatment might be due to differences between the groups in terms of their environmental conditions or members' characteristics.

Finally, nonexperimental designs are ones in which all variables are measured. The lack of experimental control or random assignment can make it difficult to rule out the plausible rivals to any hypothesized causal relationship. This makes them weak in internal validity. However, nonexperimental designs that rely on highly credible samples, as scored by the indicators in Table 1, have high generalizability. That is, their results are more likely to be replicated in subsequent studies. In addition, they often include a much larger number of IVs, which allows researchers to apply statistical controls to variables that cannot be physically controlled. The large number of IVs and DVs in such a study can be presented in a correlation matrix that reports each variable's mean, standard deviation, and reliability

Table 1   Sample Credibility Scale

Characteristics	Score
A. Generalizability	
1. Use of geographic samples	
• Single location	0
• Several locations combined	2
• Several locations compared/limited geography	4
• Several locations compared/widespread geography	7
• The entire population or a representative sample from it	10
2. Use of special populations	
• A single sample whose bias is likely to affect study conclusions	− 5
• A single convenience sample with no apparent bias	0
• Combined convenience samples with no apparent bias	2
• Compared convenience samples with no apparent bias	4
• Compared samples from the range of population variation	7
• The entire population or a representative sample from it	10
B. Sample size	
• Sample too small to test any study objectives	0
• Sample adequate to test some, but not all, study objectives	5
• Sample adequate to test all study objectives	10
C. Discussion of sample limitations	
• No discussion of sample limitations	0
• Discussion identifies types of sample limitations	5
• Discussion assesses whether sample limitations would affect study conclusions	10
Maximum total points possible	*40*

Note: Study designs usually involve *either* geographic samples *or* special populations but can involve both.

along with its intercorrelations with the remaining variables. It is usually helpful to list the variables in their presumed causal order—typically beginning with demographic characteristics, proceeding to psychological variables, and concluding with behaviors. This yields blocks of variables whose patterns of intercorrelations are easier to discern. In particular, it facilitates an examination of each variable's construct validity. This results when theoretically related variables are correlated (i.e., have *convergent validity*) and theoretically unrelated variables are uncorrelated (i.e., have *discriminant validity*).

Reporting a complete correlation matrix (including variable means, standard deviations, and reliabilities) allows readers to examine the plausibility of rival hypotheses that might not have been considered by the researchers or reviewers prior to publication. Such post hoc analyses are difficult, if not impossible, when researchers report only regression coefficients or, only slightly more informatively, regression coefficients and the corresponding correlation coefficients. In addition, reporting a complete correlation matrix facilitates meta-analysis, which cumulates the findings of multiple studies.

CRYSTALLIZED INTELLIGENCE

Although Charles Spearman's theory of general intelligence (g) garnered a nonnegligible amount of support during the early stages of modern intelligence testing, an accumulation of empirical research over the course of the 1930s prompted R. B. Cattell to contend that g was not unitary. Rather, Cattell argued, g was more accurately described as fractionated into two factors: crystallized intelligence (g_c), or the ability to reproduce information stored in long-term memory, and fluid intelligence (g_f). Since Cattell's proposal, an impressive amount of psychometric, neurophysiological, and individual differences research has continued to support the conceptualization of g_c, although the issue of whether the g factor is or is not unitary remains an unresolved issue. The abandonment of a strict theory of general intelligence and, in its place, the advent of theories of multiple intelligence, of which g_c invariably plays an integral part, has led to the comprehensive assessment of intelligence in children and adults as applied in practice today.

Psychometric Evidence

The psychometric or statistical evidence in favor of the validity of g_c as distinct from g rests largely upon empirical results that suggested the inadequacy of Spearman's tetrad equation for the verification of g. In simple terms, several researchers noted that the development of several spatially based tests of cognitive ability during the mid-1920s and early 1930s tended to correlate with others to a disproportionate degree than would have been otherwise predicted by their correlation with verbally/education based tests (i.e., g_c). If g were the only intelligence factor, the correlations would have been uniform across all subtests, within sampling variability. The plausibility of a g_c-type factor, as distinct from g, has also been suggested based on more sophisticated analyses, such as Louis Thurstone's multiple factor analysis, which was designed to allow for the extraction of more than one factor from a correlation matrix. More recently, the observation of

a g_c factor, as distinct from g or g_f, has also been supported based on confirmatory factor analyses.

Physiological Evidence

Cattell contended that, although psychometric evidence had a place in supporting the plausibility of g_c, the neurophysiologically related evidence should be regarded as more crucial to its establishment. Foremost, there was evidence to suggest that the trajectory of cognitive ability adult development in g_c is unique among cognitive ability factors in that performance tends to increase during early adulthood (20–30) and remains stable until the age of approximately 65, after which some decrement in performance is observed. Cattell also hypothesized that individual differences in g_c would be more greatly influenced by the environment, in comparison to other cognitive ability factors. This hypothesis has been supported by behavior genetic studies, which have suggested that approximately 45% of g_c variance may be heritable, which can be contrasted to the 65% heritability estimate associated with g_f. Relatedly, performance on g_c-like tests tends to be relatively resistant to brain injury and disease. Consequently, g_c-type tests are referred to as *hold tests* in the area of neuropsychology and frequently form the foundation for an estimate of premorbid IQ in many neuropsychological assessments. Although relatively resistant to brain damage, g_c performance has been empirically implicated to be mediated by Broca's area, which is an area of the left hemisphere of the brain that does not appear to need to be intact to perform other cognitive ability tasks. Also, in many neuropsychological cases, recovery in performance on g_c-type tests can be expected in those who have attained physical maturity. This last empirical observation supported Cattell's investment theory of intelligence, which posits that individual differences in g_c are due to individual differences in the previous application of g_f. For this reason, a positive correlation of approximately .50 is often observed between g_c and g_f. Thus, in combination with individual differences in g_f capacity, individual differences in g_c were considered to arise because of nonintellective factors such as motivation, socioeconomic status, education, and personality.

Personality and g_c

Although little research has specifically examined motivational processes that may affect performance on g_c tests, some research has examined personality dimensions as predictors of intelligence. The more recent research has focused on the personality dimension of Openness to Experience (a.k.a. Intellect and Culture). Theoretically, it would be expected that those motivated or naturally receptive to novel experiences and ideas may accumulate more knowledge than those who are less naturally disposed to such experiences. Earlier research based on bivariate correlations reported effects in the range of .25 to .30 between measures of Openness and g_c-type measures such as Vocabulary and General Information. More recently, however, the hypothesis has been tested based on structural equation models specifically constructed to partition g_c latent variable variance as distinct from g factor variance, as the two sources of variance are confounded with any measure of g_c. The structural equation model research suggests that the association between Openness to Experience and intelligence is due to g rather than g_c. Overall, the effects tend to be small, and there is some suggestion that not all elements of Openness to Experience may be associated with intelligence. In fact, certain elements of Openness, such as Openness to Feelings, may be correlated negatively with intelligence. Further refinement of personality measurement may be needed before this area of research may be expected to progress.

The Measurement of g_c: Compliments and Criticisms

Crystallized intelligence tests are perhaps the group of cognitive ability tests that tends to be associated with the best psychometric properties. With respect to internal consistency reliability, tests such as Vocabulary and General Information are very typically in the high .90s. Relatedly, the factorial nature of the items associated with typical g_c tests appear to be invariably unidimensional, an assertion that cannot be made justifiably about typical g_f tests (e.g., Raven's). Furthermore, the measurement of g_c has proven to be amenable in both oral forms and group-based/multiple-choice formats.

Scores derived from measures of g_c have, however, been criticized for being heavily confounded by social variables such as educational opportunity and socioeconomic status. They have also been described as culture specific, as commonly administered g_c tests tend to be based on one particular language. These

criticisms provided a nonnegligible amount of the impetus for the development of "culture-free" tests such as Cattell's Culture Fair test. However, some commentators have argued that typical g_c tests may not necessarily be as biased as commonly considered.

Consider a vocabulary (word knowledge) test, which may be considered one of the most valid g_c tests. A typical vocabulary test consists of several words that can be discriminated on at least two psychometric bases: (1) item difficulty and (2) item reliability. Item difficulty in the context of a vocabulary test is predicated upon the assessment of the frequency with which particular words in a language are found to appear in commonly available printed material (newspapers, magazines, books). Item reliability may be assessed by calculating item-total correlations for each item. It has been argued that g_c items that were biased by environmental opportunity would evidence low item-total correlations. Consequently, test developers can (and do) exclude such items from their published inventories of intelligence.

It has been contended that g_c and verbal intelligence are effectively two terms that refer to the same construct. However, this assertion should be viewed as, at least, theoretically untenable, as verbally based items of intelligence may be designed to be eductive (i.e., g_f) or reproductive (g_c) in nature. The critical distinction between two verbally based items that are respectively eductive and reproductive in nature pertains to whether the words that make up the item should reasonably be assumed to be known by the population for which the test has been designed. For example, the "analogies" item, "Big is to small as tall is to ____" contains words and a solution word that are extremely high in frequency usage in the English language. To solve the problem requires almost exclusively the capacity to educe relations. In contrast, the analogies item, "The Stranger is to Camus as The Metamorphosis is to ____" contains information that is not found in English-language usage with high frequency. Consequently, the item requires a nonnegligible amount of g_c to solve. Thus, although both items are verbal in nature, the first item does not measure g_c.

As noted above, g_c tests within popular intelligence batteries tend to be exclusively verbally based. However, spatially based tasks conceivably could be devised to measure g_c. Although a spatially based crystallized intelligence task may not be expected to be any less culturally biased than a verbally based g_c test, it may be argued to be more justifiable to measure g_c via more than one mode of communication or sense modality.

Factorial Status of g_c

A substantial amount of empirical research has attempted to quantify the association between g_c and g in comparison to other lower-order factors. Within the three-stratum model of intelligence, which consists of eight second-stratum factors, g_c is placed as the second most closely associated second-stratum factor to the third-stratum g factor. Given that g_c is often considered nonnegligibly influenced by the environment, a strong association between g_c and g may seem incongruent. Various researchers have attempted to reconcile this apparent contradiction by suggesting that the accumulation of word knowledge over time is not largely based upon specific instruction from parent/teacher to child/student (i.e., rote learning). Instead, the accumulation of word knowledge is based on a process of discerning or inducing the meaning of a word based on the context in which it is used—for example, based on the meaning of other words used in the sentence/paragraph, and/or based on the meaning of portions of the unknown word that are similar to other, previously learned words. Thus, the process of accumulating word knowledge would be expected to be nonnegligibly based on an eductive process, hence the strong association between g_c and g within higher-order models of intelligence. For this reason, it has been argued that no subtest should be considered a pure measure of g_c, as any valid g_c subtests would be expected to consist of both g_c- and g-related variance.

CULTURAL DEFICIT MODEL

The *cultural deficit model* (hereafter referred to as the deficit model) is the perspective that minority group members are different because their culture is deficient in important ways from the dominant majority group. The field of educational psychology has long been interested in understanding why racially different, non-White children perform differently in school, with an emphasis on academic underachievement. The deficit model has been important in the evolution of thinking about this important social issue. Hence, the deficit model asserts that racial/ethnic minority groups do not achieve as well as their White majority peers in school and life because their family culture is dysfunctional and lacking important characteristics compared to the White American culture. Other names for the deficit model have been *cultural disadvantage*, *cultural underclass*, *cultural poverty*, *culturally deprived*, and *social pathology.* In the following paragraphs, the deficit model is discussed further along with examples from schools and education.

Evolution of Thinking About Difference

Historically, U.S. researchers from various disciplines have been interested in racial differences and explaining why they exist. African Americans have been the primary focus of these early efforts since the mid-to-late 1800s. The prevailing view during these times was the *biological deficit* or *genetically deficient model:* Racial differences were caused by insufficient internal abilities, such as poor intelligence and/or inferior genes. In contrast to the biological explanation, the focus shifted to sociocultural factors related to culture and poverty—the cultural deficit model.

To explain academic achievement disparities of racial/ethnic minority children, the cultural deficit model asserts that minority cultural values are dysfunctional, which is the primary reason minority children fail to achieve academically and occupationally. The deficit model further assumes that minorities do not value education as a means of social and financial mobility. Finally, because cultural values are passed on through the family, the minority family is also viewed to be dysfunctional and insufficient.

The deficit model had become very popular during the 1960s and 1970s and influenced educational and psychological theory and research, and even political views. The deficit model's advantage is that it has clear practical implications: Schools need to provide children with the cultural experiences that they are missing at home, and help families to function better. For example, federal Head Start programs were founded to help poor minority children who came from culturally deprived families and homes.

Criticisms of the deficit model are numerous. First, the deficit model is unfair to minority children and their families, focusing the blame on their culture. The deficit model is also inaccurate because it deemphasizes the powerful effects of poverty on the families, schools, and neighborhoods, which synergistically affect academic achievement and occupational attainment. It also strongly implied that White middle-class values are superior. Fourth, the deficit model became equated with pathology in which a group's cultural values, families, or lifestyles transmit the pathology. Finally, the deficit model has limitations for scholarship because it is too narrow as an explanatory model (i.e., rigidly blames the family) for the academic underachievement of poor minority children. In short, the deficit model's negative effects are that children were narrowly viewed as "deprived" and their families became "disadvantaged," "dysfunctional," and "pathological."

In response to these criticisms, the *culturally diverse* or *cultural difference model* has more recently become popular. In this view, minority children and their cultures are different yet valuable. Alternative lifestyles and belonging to more than one culture (e.g, biculturalism) are viewed as viably different from mainstream culture and lifestyles. However, even this model, if viewed narrowly, can result in negative effects (rigidly blaming the school for academic problems) and may not account for the true complexity of how children learn and develop over time within important environments (classroom, school, peer groups, families, communities).

Social and Educational Implications

At the current time, much more attention is being given to the culturally diverse perspective formally within educational psychology and education. For example, a multifaceted approach to race and education is

becoming more popular (e.g., culturally relevant teaching and pedagogy). Still, although the exact terms of the deficit model may not be used anymore, the underlying perspective and associated beliefs of the deficit model are alive and well in society and various public service disciplines. It is critical to understand these varying perspectives and beliefs regarding the culturally different because the racial makeup of the United States is continually changing.

Cultural Diversity

Cultural diversity is the modern term giving recognition and value to the multiplicity of peoples, customs, languages, heritages, and cognitive orientations woven in the rich fabric of American society. Once thought to be a melting pot, the character of the United States is now recognized as reflecting a cultural plurality, wherein particular groups maintain their distinctive character and identity with respect and pride. Cultural diversity is celebrated as a strength, because these groups contribute their knowledge perspectives, experiences, and practices toward the advancement of the nation and humankind. The value of cultural diversity is reflected in the founding of the nation as a refuge from persecution, the recognition that all are created equal, and the prohibition against discrimination reflected in the Constitution. Cultural diversity is relevant, then, to every aspect of daily life, including education and human service. A monocultural approach to professional service is not only discriminatory but can be detrimental to the client and often a waste of the resources of the professional. This entry explores the origin of cultural diversity, as well as the essential concepts that contribute to its appropriate application to the practice of educational psychology.

Origin of Diversity

The rich cultural diversity of the United States is derived from its earliest settlement in 1607, when European emigrants from England, Spain, Sweden, Holland, and France settled with the indigenous American Indians along the Atlantic coast. Africans arrived shortly thereafter in 1619 during the slave trade. Although the settlers lived as separate colonies for 177 years, until the end of the Revolutionary War, it was not always a peaceful existence. American Indians were displaced, and wars and rebellions raged among the settlers until the British and French prevailed. Although the nation today is often associated with equality, democracy, religious tolerance, and human rights for all, history documents a sinuous journey toward these ideals.

In the next century, as the nation began to attract more settlers to its expanding territories, immigrants further increased the diversity. However, the immigration laws did not always honor the democratic ideals of the founding fathers. The Naturalization Act of 1790 restricted immigration to "free White persons." Similar exclusionary laws, such as the Chinese Exclusion Act of 1882; the Immigration Act of 1907, which stemmed the flow of Mexicans; and several other laws enacted between 1917 and 1952 excluded, set quotas, or gave preference to immigrants of specific nations until the Immigration Acts of 1968 and 1976 eliminated such discrimination. Even today, the Patriot Act of 2001 permits exclusionary practices aimed at obstructing terrorism. Thus, either by default or design, the nation is today a patchwork of cultural diversity. There is no doubt that since its founding, the United States has remained culturally pluralistic. This concept acknowledges that American society comprises diverse and distinct ethnic subsocieties that maintain their group identity.

Terminology

At this juncture, it is necessary to distinguish ethnicity from culture. The anthropological notion of culture is

an abstract concept that refers to learned rules of behavior and interaction, plus the values and beliefs that underlie the overt actions of an individual or a group of similar individuals that distinguish and identify members as a part of the group. *Ethnicity* refers to the more concrete, unchangeable outward characteristics of culture such as race, national origin, or ancestry, which are the conscious focus, not so much by members of the group, but by others. Thus, culture is an internal abstraction and ethnicity is an other-directed categorization.

Although the term *ethnicity* is popularly associated with minority groups, and sometimes religious or language groups, the further distinction of these terms is necessary. A minority group is typically defined in relation to its numerical proportion in the general population together with subtle implications related to its history, power, and dominance. However, although a numerical majority, women are sometimes categorized as a minority group particularly with regard to labor, political influence, and economic power. Specific religious groups are perceived as ethnic groups, such as Jews and the Amish people popularly known as Pennsylvania Dutch. Similar to Jews, the Amish are not "ethnically" distinct. However, their religious and cultural practices distinguish them from mainstream society. These cases exemplify the complexity of conceptually separating religion and ethnicity for some groups.

In some cases, nationality corresponds broadly to ethnicity, as in the example of Americans of recent German, Swedish, or Dutch descent. Such distinctions are readily observable, especially when national origin and language group are the same. However, a major exception is observed in the case of Spanish speakers, also known as Hispanic or Latino/a. Within this language group are subsocieties that can be linguistically, ethnically, nationally, or culturally distinct. It is important to note that not all Spanish speakers are immigrants to the United States. Historically, Spanish speakers inhabited the territories that today include Florida, Texas, California, Arizona, and New Mexico, as well as parts of Louisiana, and the midwestern and northwestern states.

Even the terms *Hispanic* and *Latino/a* reflect the diversity of cultures. *Hispanic*, often used interchangeably with *Latino/a*, is a designation adopted by the U.S. Census Bureau to classify any individual of Spanish ancestry. Contrastively, *Latino/a* is a term adopted recently by younger non-European individuals to express their cultural distinction and pride.

Inextricably associated with cultural diversity is linguistic diversity. Currently, two main languages, English and Spanish, predominate in the United States, although there are more than 100 languages represented among its bilingual citizenry. During the European wave of immigration, assimilation was favored over preservation of the original culture and language. English was valued as the lingua franca and unofficial national tongue. High importance was attributed to learning English, especially Standard English, as the required medium for identification and socioeconomic advancement. However, for particular groups, such as African Americans, Hispanics, and American Indians, language preservation is a source of cultural identity, pride, and solidarity. Currently, Spanish has gained recognition in government, social, and business interactions, and bilingualism has gained a measure of acceptance with the latest wave of immigrants since the 1990s.

The language of African Americans, known as African American English (AAE) and colloquially known as Ebonics, has been the subject of social and political concern, as well as educational research. A dialect historically thought to be the faulty learning of, or misuse of, Standard English, linguistic scholars presently acknowledge the origin of AAE as a fully developed linguistic system derived from a Creole of Western African languages together with English, Dutch, Portuguese, and other European languages spoken by the colonizers of the African continent. Contrary to popular thought, AAE was transported to the United States and the Caribbean during the Middle Passage, survived among the African slaves, and has undergone a process of decreolization, or merging with Standard English, since the abolition of slavery. Similar influences of this linguistic merging are observed in Haitian Kreyol, Afro-Brazilian Portuguese, and Afro-Cuban Spanish. Although it has been erroneously asserted that AAE affects intelligence, academic performance, and literacy acquisition, direct evidence for this claim is generally lacking, as the seeming effects are more likely due to racism; de facto segregation; and other, more complex factors.

Another prominent component of cultural diversity is cognitive orientation, most specifically sexual preference. Research has shed light on the possibility of a biological genesis for homosexuality. Certainly, most practicing homosexuals will reveal that their sexual proclivity is no more subject to their own selection than for heterosexuals. There is no argument that open homosexuals identify as a cultural group.

A final cultural group for consideration has ties across all others previously discussed. This group is known as Deaf Culture. Congenitally deaf individuals qualify as a cultural group in every sense of the word. Historically classified as disabled, congenitally deaf individuals have recently asserted their right to be recognized as fully functional members of society. A full understanding of deaf culture requires examination of the dimensions of deafness.

Deafness can be congenital or acquired. Generally, individuals with acquired deafness are classified as members of the hearing community, and they accept their acquired condition as a disability. The rights of these individuals are protected under the Americans with Disabilities Act. Much like individuals with a partial hearing loss, they usually do not identify with Deaf Culture. Unlike their congenitally deaf counterparts, they prefer oral communication for full interaction with the hearing community.

Contrastively, members of Deaf Culture prefer American Sign Language (ASL) as their medium of communication. Thus, Deaf Culture can also be classified as a linguistic group. Historically, teaching oral communication and efforts considered as attempts to correct a disability, including speech therapy and cochlear implants, have been rejected.

A major characteristic of Deaf Culture is self-determination. Much like the Amish, assimilation into general society, especially in education, is not the preference as deaf individuals prefer separate education in deaf schools wherein the culture is practiced and preserved. Cultural conflict can arise when a deaf child is born to hearing parents who promote assimilation.

Having discussed the major cultural groups and the salient issues within the context of society, this entry now examines the application of this information to professional practice using three case examples. The reader should bear in mind that the rules of intercultural interaction are dynamic, and extremely few universals apply.

Professional Issues

Case Example 1

An Islamic female student in counseling psychology is assigned to practicum with an adult male client. Privacy rights of the client require that the session be held in a closed environment. The student insists that this would violate her religion. The instructor advises the student to transfer to another field.

Cultural conflict arises when the rights guaranteed to one individual impinge upon the perceived rights of another. Certainly, the client is guaranteed privacy, yet the requirement goes against the religious practices of the student who has the similar right to receive her education. Often, these cases find their way to the judicial system with much toil and chagrin. However, in the professional setting, a sense of mutual compromise should prevail. Two scenarios represent a possible compromise.

1. The client's right to privacy would not be violated by the presence of the instructor. The instructor could be present in the room during the counseling session.

2. With the door ajar, the counseling area could be sectioned off, and access to the entire area restricted during the time of the session.

Note that in each scenario, protection of the client's rights is the priority because these rights are mandated by law.

Case Example 2

A deaf student with a cochlear implant (the reader may substitute an individual who stutters, or a speaker with a foreign accent) is accepted in the speech-language pathology program. The student is not permitted to conduct clinical practicum and is granted a "nonclinical degree." This degree will not enable the student to practice in the field.

Has the university violated the student's rights? This question is complex and remains controversial. The university will grant the student a degree, but the student will not be qualified to practice in the profession. Whether the university's action is unethical depends upon a strict or loose interpretation of the purpose of the degree. With a strict interpretation, one may argue that the degree is but one criterion for professional practice. And because there are other certification requirements, even the regular clinical degree does not guarantee entry into the profession. With a loose interpretation, one would argue that without the required practicum and the regular clinical degree at a minimum, the university itself has restricted the student from professional practice.

Generally, in cases such as this wherein discrimination in admission policies is prohibited, the burden rests with the university to provide the necessary accommodations to afford the student equal access to the degree and the profession.

Case Example 3

In compliance with a mandate to achieve diversity in the workforce, an elementary school hires African American, Hispanic, Asian, and Middle Eastern teachers. Several parents state to the principal that they desire for their children to be taught only by White teachers.

Should the principal comply with this request? Perhaps there is a temptation to comply with the parents' request because the action would not be openly observable and no one would be hurt. Moreover, parents often select their child's teacher based on other, different characteristics.

It can be argued that such subtle forms of discrimination are the most pernicious. *White privilege* is the term used to depict the covert advantage afforded to Whites that is characteristically unknown to those against whom it discriminates. An additional subtle form of discrimination relates to the perceived value of an individual to the society; for example, the death of, or an atrocity involving, a White person arouses a greater public reaction than the same for a non-White person. For example, a missing African American teenager may barely receive mention in the media, whereas a missing White teenager may be cause for an Amber Alert.

In the foregoing case example, personal and professional ethics should dictate the principal's decision not to comply with the parent's request. The ravages of subtle discrimination are borne by the profession and the society inasmuch as their cumulative effects promote cultural divisiveness and ill will.

Political Incorrectness

Several noted professionals, celebrities, and public figures have had their careers ruined by pejorative slips of the tongue regarding cultural groups. Either as an ethnic joke overheard, slang use of a name, or stereotypic generalization, political incorrectness has become intolerable. Political incorrectness is regarded as a manifestation of covert prejudice. Revelation of such prejudice renders anyone of professional position, or social or political influence, untrustworthy in their overt actions or decisions. As a case example, in response to violence at a predominantly White suburban elite high school, a White principal reassured the parents that the incident was "Black on Black" crime. Only the overwhelming support of African American parents citing previous instances of cultural fairness saved the principal's career from destruction.

Political incorrectness is dictated by the principle of "Once spoken, there can be no retraction." Consider the recent example of the political candidate who gained notoriety by referring to his mother endearingly with a pejorative slang term. Similarly, a different candidate alluded to his African American opponent as "articulate." Although covert prejudice in these two examples may not have necessarily been intended, it was the irresponsibility of the speaker that was not tolerated.

Intercultural interaction requires knowledge of insider versus outsider rules of communication and conduct. For example, it may not be taboo for the slang pejorative term for African Americans to be used by African Americans in casual communication. However, any use of the same term by a non–African American can evoke immense pain, and often a severe negative reaction. Suffice that African Americans only can sense the deep historical assault associated with the term, and ironically, insider use may somehow reduce the impact of the assault. However, this emotion is not transferable, so any use of the term by an outsider is considered intolerable.

Test Bias

A major professional issue with regard to cultural diversity is test bias. Most professions rely on standardized tests for decisions ranging from determining who requires services to measuring the competency of professionals. A standardized test is one that is scored on the basis of the performance of a norming population. Rarely is this population reflective of the numerical proportion of every cultural group. Hence, standardized tests present a bias if they unfairly overgeneralize or do not reflect appropriate sensitivity in regard to a specific cultural group. This is not to imply that a standardized test is never accurate for individuals from cultural groups. But wherever systematic results are reflected for a large number of individuals from a cultural group, a bias should be

suspected. Such biases lead to misdiagnosis and inappropriate services.

There are several possible sources of cultural bias. A major source is value bias. Value bias is reflected in test items that represent a mismatch in the cognitive assumptions of the test maker and the examinee. An example of value bias is demonstrated in the case when the examiner expects the examinee to state answers using full sentences or narrative scenarios, and the examinee provides a one-word response and presumes that the examiner can fill in the remainder. This phenomenon of "shared knowledge" is often observed in high-context/low-verbal cultural groups such as African Americans, Hispanics, and American Indians. A high-context/low-verbal culture relies on the context, environment, and nonverbal responses. Thus, fewer words are necessary to effect communication.

Situational bias is often overlooked when examining children and adults with standardized tests. Situational bias refers to the social context, format, assumptions, and implicit rules of the testing moment. Many students report that they do not perform well on multiple-choice examinations because they are not accustomed to making one correct choice from a multitude of possibilities. Also, when the test environment assumes a time-restricted or competitive nature, cultural groups such as American Indians and some Hispanics may subconsciously reject the testing exercise in its entirety. In other cases of situational bias, there may be a fallacy that the examinee will approach the test as her or his "ideal self," as characterized by the popular adage "Putting the best foot forward." A tendency of several cultural groups is to take the test at face value and respond from a deeply personal vantage. The wrong answer is incurred, not because the examinee did not possess the answer, but because the perception of the right answer reflected a cultural mismatch of expectations.

Another type of bias is known as linguistic bias. Linguistic bias may involve the grammatical constructions within the test items, wording of the instructions, or even scoring of the responses. The results of linguistic bias reflect the interference of the examinee's native language or dialect.

The use of culturally and linguistically discriminatory instruments is prohibited by law. However, compliance may be impossible wherever truly culturally fair and culturally sensitive instruments do not exist. The solution is that professionals should recognize possible biases, apply appropriate accommodations, refrain from total reliance on standardized test scores, and demonstrate the validity of test results with additional nontest evidence.

Intelligence and Cognitive Style

The debate on culture and intelligence has existed for more than a millennium. At one time, Europeans were thought to be less intelligent than Africans. In the United States, the debate emerged in the 1960s, and again in the 1980s, as Whites were observed to score higher on traditional intelligence tests than African Americans. Toward the resolution of the debate, Howard Garner first advanced the psychological theory of multiple intelligences in 1983. Gardner posited that the typical constructs used to define and measure intelligence were too narrow. To date, he has identified eight separate intelligences—linguistic, logical-mathematical, spatial, bodily-kinesthetic, musical, naturalistic, intrapersonal, and interpersonal—for which individuals variously demonstrate proclivities. Few intelligence types listed by Gardner lend themselves to academic performance.

Modern theories of the relationship of intelligence and culture espouse either the nature or nurture position. Nature theorists follow the assumption that intelligence is congenital, biological, and genetic. Certainly, congenital abnormalities such as mental retardation support their position. Nurture theorists consider the interplay of environmental factors such as nutrition, parental education, home environment, socioeconomic level, cultural beliefs, motivation, language barriers, quality of education, health, racism, and lack of positive role models as determinants of intellectual ability.

Cognitive style, also known as learning style or conceptual style, supports the notion of multiple intelligences by recognition that individuals encode and decode input information and solve problems according to their predominant tendency of thinking and reasoning. Cognitive styles have been broadly associated with various cultures, albeit without absolute reference. Rosalie Cohen is one proponent who proposes a dichotomous model of cognitive style. In this model, the Analytic learning style, which favors White, middle-class individuals, is identified by the tendency toward stimulus sensitivity, focus on detail, objectivity, and lengthened attention span. Contrastively, the Relational learning style, which characterizes low-income minority groups, features the tendency toward subjective learning, learning in a cooperative social context, personalized content, and shortened attention span.

Cohen describes how the classroom favors the Analytic style, leaving Relational students at great disadvantage. For example, teaching models used in traditional American classrooms require the use of linguistic, logical-mathematical, and interpersonal intelligences, which are associated with the Analytic cognitive style.

Achievement Gap

The *achievement gap* refers to the performance differential in academic performance wherein racial, linguistic, and cultural minorities lag behind their mainstream counterparts on such indicators as reading achievement, grade point average, and dropout rate. It is observed that by the time they reach twelfth grade, provided they do, minority students are 4 years behind in their achievement, with African American and Latino students demonstrating skills in English, math, and science similar to those of eighth-grade White students. Similarly, deaf students typically fail to achieve grade-appropriate reading levels.

It is evident from national measurements collected over the past three decades by the National Assessment of Educational Progress that there has been little change, even when the socioeconomic level is controlled. Schools have witnessed an overrepresentation of minorities in special education programs, and a similar underrepresentation in programs for the gifted and talented. It is not known how much the issue of test bias, and the overrepresentation in special education, contribute to this situation.

Although it is generally accepted that the achievement disparities for African Americans and Latinos reflect the confluence of a multitude of variables, including language, income, family structure, schooling, and cultural factors, these factors alone do not adequately explain the genesis of the gap. Hence, school reform has been a top priority since the mid-1980s. This movement has enjoyed many successes, but significant challenges remain.

Health Disparities

The inferior health status of minority populations in the United States is well documented. Compared to Whites, African Americans, Latinos, Asians, and American Indians have a greater prevalence of diseases, higher mortality, shorter life expectancy, and poorer treatment outcomes. Diseases and chronic conditions, including cancer, hypertension, asthma, diabetes, and lead poisoning, occur with much greater frequency and are more likely to result in hospitalization and death in African Americans and Latinos. HIV/AIDS is a condition historically associated with the male homosexual community, yet new cases are increasing fastest among minorities, particularly African American women and young adults of 18–25 years.

The causes of health disparities can be categorized in four major areas: genetics; cultural, socioeconomic, and environmental factors; access to health care services; and quality of the care provided. With regard to genetics, greater emphasis is now being placed on familial predisposition to illness. Particular cancers, hypertension, obesity, and diabetes have been observed through successive generations. Cultural practices, such as unhealthy dietary intake and a sedentary lifestyle, together with genetics increase the probability of disease conditions. Particular conditions, such as fetal alcoholism syndrome in American Indians, also reflect the influence of cultural practices and genetics.

Cultural factors also include beliefs and attitudes about the body and life, as well as preference for home remedies, which are all characteristic of minority populations. For example, African Americans, Latinos, Asians, and American Indians are more likely to seek holistic or nontraditional remedies such as herbalists, faith healers, and shamans.

Socioeconomic causes of health disparities include lack of insurance coverage, inadequate insurance coverage, lack of transportation, and lack of a consistent source of health care. Minorities are more likely to use emergency and acute care as a last-resort effort, rather than pursue regular visits to a physician.

Linguistic barriers and lack of health information also contribute to health disparities for minority populations. The linguistic barrier is particularly apparent for Deaf Culture and bilingual immigrants. Immigrants also encounter legal barriers because federal law prohibits Medicaid coverage until individuals have resided in the country for 5 years. These barriers restrict minority populations' access to health care.

The burden of health disparities is not entirely the responsibility of minority care receivers. Scarcity of health workers, especially in rural areas, as well as lack of diversity in the health care workforce and lack of cultural competence among workers are also barriers related to quality of health care. The issues associated with health disparities are currently being addressed assiduously, with their complete elimination as a national goal.

Professional Service Delivery

Every culture displays its own unique qualities. But no culture is superior to another because each culture functions to preserve the well-being and highest quality of life for its members within the context of its unique worldview. Culture competency requires a knowledge of the ideas discussed in this entry, plus the acknowledgment that every individual deserves the highest level of professional service. An appreciation of cultural differences is an opportunity for self-enlightenment, and the use of culturally relative and culturally competent methods of service delivery is the key to a stronger and more effective profession.

CULTURE

Although various attempts have been made to define *culture*, traditional definitions of culture have been very limited in scope. Historically, *culture* has been defined as a series of traits shared by a group of individuals. That is, the concept of culture has been understood as shared norms that shape individual behavior. These behaviors have been interpreted as being standardized rules for a group of individuals. Despite the unifying traits that organize and, at times, define cultural groups, culture has been traditionally construed as a monolithic variable that is stagnant or fixed both in time and space. Defining *culture* in such a way fuels a discourse that essentializes individuals of particular cultural groups by universalizing the existence of a uniform set of traits that is shared by each group. What is problematic is how this definition reinforces a perspective that universalizes and/or standardizes group norms, behaviors, and ideologies. Doing so perpetuates a discourse that reinforces these behaviors and ideologies as being static and neither fluid nor dynamic.

Emerging, however, are attempts to understand culture as the everyday practices and beliefs that individuals embody and display through behaviors and practices. This perspective reinforces discourses suggesting that individuals communicate their culture through language, rituals, religious beliefs, value systems, traditions, and other beliefs. In other words, culture has been constructed as a way of "doing life" or engaging in life-centered activities. Given this orientation, culture is a socially constructed concept that is dynamic, emergent, interactional, and multidimensional; it is not constant, fixed, or compartmentalized within a particular category or definition.

Rather than focus on what culture is and is not, the aim of this entry is to reflect on the practices in which individuals engage within a particular context and within a particular moment in time. Embedded within this perspective is an affirmation of how individuals engage in life and how individuals discuss their engagement. This entry examines the construct *culture* by moving beyond uniform categorizations of shared group cultures that tend to essentialize groups and their respective practices. The entry's purpose is threefold. First, it provides a general understanding of culture within the field of educational psychology. The complexities of culture are then illustrated by examining how research reports learning styles and the variation in learning outcomes. Second, a critical discussion is presented on the complexity that arises when using broad definitions of culture and ethnicity, especially when analyzing and discussing specific cultural groups. A discussion highlighting the strengths and weaknesses of using broad-based terms to define specific cultural groups when designing, conducting, and interpreting empirical research follows. Finally, there is a discussion on how constructs such as ethnicity and race are often used interchangeably with constructs such as culture.

Culture and Educational Psychology

Culture is a complex process that, in the broadest sense, can be defined as the means by which a group of individuals engages in daily activities over the life course. It is the commonalities such as norms, beliefs, language, and values that are shared by a group of individuals that shape culture. Moreover, culture is considered to be a dynamic and multidimensional source of influence on the developmental processes within a community. Understanding culture as a sociocultural

construct within a particular context reinforces the importance of examining both macro and micro dimensions that affect how culture is operationalized. Of significance to the field of educational psychology is how learning variations among school-age students and culture get operationalized and are understood.

Given this, recent research has advocated that individual development is not affected by culture. Rather, individuals develop as they participate in activities and/or daily practices that they construct, yet practices also include an inheritance of ideas from previous generations. This perspective centers on an ideology that positions individuals as having an impact on culture rather than culture changing the individuals. Such an approach also debunks the ideology that culture is a category into which individuals fit. It reinforces the notion that culture encompasses the cultural practices lived by individuals.

Historically, the discrepancy in academic achievement among students in the United States has been attributed to the students' culture. Research reports that the majority of students who have low academic achievement outcomes are from poor and working-class backgrounds and tend to be students of color. Suggesting culture as the cause for academic achievement differences reinforces a paradigm that places the individual's culture at the center of the problem. That is, a deficit model paradigm is used to understand the learning variabilities and outcomes evidenced among students. Of serious concern is how such a discourse frames the problem as being culturally based (i.e., an individual's culture). Such reasoning suggests that the individual's culture must change because it is the "problem," and thus educational institutions and U.S. society are absolved of any responsibility. Such a discourse also reinforces an assimilationist approach, suggesting that individuals who are not from the dominant culture must assimilate and reflect practices that are in alignment with the dominant culture. For example, it is common to hear how ineffective parenting or lack of parental interest in the child's schooling is the main cause for low-performing students. The responsibility of improving the student's learning outcomes is placed on the individual and responsibility is removed from the educational system (i.e., schools) and U.S. society. Although strides have been made to eliminate deficit models that frame academic achievement disparities, they are still salient within the U.S. educational system and evident in some policy reports.

A recent example of an approach used to overcome culturally deficit theoretical frameworks to understand learning variabilities among children and youth in U.S. schools is the cultural historical approach. Gutierrez and Rogoff argue that a

> cultural historical approach offers a way to get beyond a widespread assumption that characteristics of cultural groups are located within individuals as "carriers" of culture—an assumption that creates problems, especially as research on cultural styles of ethnic (or racial) groups is applied in schools. (p. 19)

For example, cultural styles are no longer viewed as deficits because they are examined from the community's participant's perspective. Alternative models suggest omitting the culture embodied by participants from the analysis. Such models favor paradigms that deny cultural variations, implicitly suggesting that the cultural practices of the dominant group were the norm and the developmental trajectories and learning outcomes for the dominant group (i.e., White middle class) were normalized.

The movement of educators to gain awareness and understand the culture of their students was also a promising attempt to discredit the cultural deficit approach. Of concern was how school, home, and/or community cultures juxtapose each other. Knowing this, solutions were crafted that focused on training teachers to engage in cultural patterns that were in sync with the students' cultural worlds. Implicit within this view is how cultural groups are understood as being confined by normative practices that are clustered together to form a unifying culture. Such definitions affect how educational institutions operationalize their curricula. For example, pre-service teacher education programs may train teachers to be culturally sensitive.

Culture, Race, and Ethnicity

Historical definitions of culture, suggesting that individuals from similar cultural groups display similar behaviors based on traits, perpetuate and reinforce stereotypical cultural behaviors. When defined by traits, culture suggests that the traits occur independently of people. Defining culture as a series of traits fuels a framework that embraces a deficit approach when examining learning variations among students of color. Serious implications arise when one defines culture as

a series of traits and variations are attributed to distinction in cultural traits among cultural groups. For example, this approach reinforces cultural traits as fixed—static constructs that remain constant across time and space. Recent work such as that by Banks and Gay examine cultures within a particular context and at a particular point in time, emphasizing the dynamic and more situational view of cultural practices.

Given this, individuals *live* culture. Thus, culture is a process that is dynamic, interactional, and contextual, one that is constantly changing over time. When culture is examined at the macro societal level, the intersection of race, class, and gender becomes noteworthy. Furthermore, historical and political issues become part of the analysis in understanding how culture (trans)forms over time. Recent legislation, such as No Child Left Behind, has affected the experience of children and youth in U.S. schools. That is, the high-stakes testing assessment implemented in schools has changed the learning culture for school-age children.

Similar to culture, race is also a socially constructed variable whereby the stratification of groups, community, and individuals becomes especially noteworthy. Although some researchers have argued that group labels reflect transformations in awareness in the sociopolitical milieu, these group labels are also used by the privileged in our society to impose negative attitudes and oppression onto the various ethnic working-class populations. It is through the social construction of group labels that racial formations are created and understood. These racial formations have become what we understand as ethnicity.

Ethnicity has been defined as a collective identity and is often explained in terms of national group membership and/or religious affiliations. Hence, a distinction can be made when defining and interpreting racial categories given the unique cultural affiliations that mark ethnicity within racial subgroups. More specifically, ethnicity is a critical element of race in that it is the foundation of diversity within and between racial categories. For instance, although "Hispanic American" constitutes a "racial category" in the United States, there is great ethnic diversity among Hispanic Americans that is often overlooked. For example, those of Cuban, Puerto Rican, Mexican, and Central American descent have cultural distinctions that mark how life is lived.

Given the complexity that underlies definitions of culture and race, it is critical that scholars begin to "unpackage" definitions of ethnicity as they attempt to study cultural contexts. Individuals must take notice of their position in society and articulate their marginalization, which is rooted in ethnicity, social class, migration, and citizenship. The complexity of ethnicity is revealed as individual lives are contextualized within the sociopolitical and historical experiences these individuals and their communities have endured. Acknowledging intragroup differences consequently reveals the multiplicity of experiences subsumed under the broad-based term *Latina/o*.

Complexity of Broad Definitions

Of particular importance is how researchers study cultural context. Given how culture is defined, it would be important for researchers to study cultural context in the making or as it is being lived, rather than as a cultural object or a stagnant, idealized concept. There are several strengths in using a broad definition of culture and ethnicity when studying ethnic group populations. For example, researchers can obtain a sample of participants who affiliate with the group label of Native American more readily than with specific tribal affiliations like Navajo Indians. Such general sample populations are more easily accessible when geographical location is not considered. For example, Latinas/os in California might include a higher concentration of Chicanos or recent emigrants from Mexico than, say, a population of Latinas/os in Massachusetts, where there might be a higher concentration of Cubans and Puerto Ricans. Hence, researchers who use a broad definition of culture and ethnicity and conduct research in either location would still be able to make claims about the Latina/o population despite the different subgroup affiliations. The major strengths of such studies can be generally described as follows:

1. Increased availability and accessibility of sample populations to be studied

2. More resources and information pertaining to the population being studied, because information is not always aggregated by ethnicity, social class, geographic location, immigration, and so on, but is subsumed under general racial categories such as "Latina/o" or "Native American" (i.e., census data, school and educational testing statistics, health and social service statistics)

3. Facilitation of discussion of individuals from multi-ethnic or mixed-race backgrounds because they are

included as members of specific racial groups (e.g., Latina/o, Native American).

Intragroup heterogeneity exists along varying positions such as ethnicity, social class, and regional identification. Such distinct and complex affiliations prevent ethnic or racial group membership from being equated into one common cultural experience. When one uses broad-based terms to characterize an individual and culture, one discounts the cultural diversity embedded within a particular ethnic group. The terms *Native American* or *Latina/o* will be used to illustrate this point.

The terms *Native American* and *Latina/o* have been socially constructed to include individuals from either Native ancestry and/or Latina/o ancestry. Despite the many core traditional values that Native Americans share across tribal groups, it should be recognized that Native Americans are a heterogeneous group. Native Americans differ vastly in their level of acceptance of and commitment to specific tribal values, beliefs, and practices through a variance of customs, language, and type of family structure.

The cultural differences that exist among the Native American populations are extensive, yet in some cases extremely subtle. However, it is not sufficient enough to distinguish these cultural differences by solely recognizing and acknowledging the sociocultural behaviors of individual Native American tribes. Rather, one must also understand Native American families through a lens that is sensitive to and understanding of the specific demographic variables. For example, the primary locale of residence, whether it is in an urban or reservation area, plays a critical role in Native American ethnic identification and instillation of cultural values. The families' socioeconomic status and family structure are also important variables to better understand contemporary Native American families.

The *Native American* term, albeit an umbrella term, does not capture the distinct cultural and spiritual traditions that make up each tribe of the more than 500 federally and state-recognized Indian nations and slightly more than 200 unrecognized Indian nations. For example, the Hopi Indians have substantially distinct traditions that differ from the Oneida Nation. Unfortunately, the cultural distinctions that exist between various tribes are often ignored and not accounted for when using broad terms such as *Native American.*

The term *Latina/o* is a broad ethnic label encompassing Puerto Ricans, Mexican Americans or Chicana/os, Cuban Americans, and any other individuals whose ancestry may be from Latin America. As in the case of Native Americans, the broad-based term *Latina/o* ignores historical, social, political, and cultural histories and traditions of the specific populations. More specifically, the term *Latina/o* camouflages the intragroup differences that exist (e.g., country of origin, generational history, familial immigration patterns and history, language preference, etc.). Usage of a broad-based term also ignores political struggles and historical experiences that each group has endured. Some groups of Latinas/os residing in the United States do not have the same historical and sociopolitical relationship to the United States as other Latina/o groups. For example, Chicanas/os and Puerto Ricans are two groups of U.S. citizens whose historical relationship to the United States were not originally shaped by immigration or forced exile, but rather by conquest and colonization. Unfortunately, broad-based terms such as *Hispanic* and *Latina/o* do not acknowledge these historical experiences, nor do such terms accurately characterize the individual lives and experiences of Chicanas/os and Puerto Ricans as legal citizens in the United States. Such examples illustrate the importance of acknowledging racial, ethnic, and geographical locations and family structure coupled with individual cultural factors, including migration, in an effort to better understand how such conditions influence one's development.

Another illustration of how broad-based ethnic terms may not accurately characterize ethnic groups is exemplified when researchers refer to a population as being of Mexican origin. This term refers to individuals who have recently immigrated to the United States, and it also includes individuals who have resided in the United States for generations coupled with individuals who resided in the United States when it was part of Mexico. Collapsing the experiences of individuals from various generations fails to acknowledge the distinct cultural experiences attributed by generational status in the United States.

Viewed in this way, the Latina/o population is too often solely characterized by its cultural relationship to its home or mother country. For example, it is assumed that Latinas/os migrating to the United States bring specific cultural traditions and familial practices as recognized in their home country. However, overlooked when making this distinction is how narratives

of migration are distinct and carry unique understandings that are dependent on the population, the population's proximity to its home country, and the regional differences that exist in the population's country of origin. Underlying each of the narratives will be the political climate that frames the discourse toward immigration and immigrants.

These generational, linguistic, regional, and economic differences are significant and should be accounted for when conducting research on developmental processes as they will account for multiple influences of our own cultural and sociohistorical locations. For example, Jeffrey Lewis points out how indigenous populations like the Mixtec, who live in Mexico and who migrate to the United States, form a different relationship with the United States than other recent emigrants from Mexico. The Mixtec are noted for their transnational migratory practices, spending equal amounts of time in both the United States and in Oaxaca, Mexico. This continual interaction with their home country creates a unique relationship with the United States such that they maintain their indigenous beliefs, language, and cultural practices because of the continual interaction with their native communities. It is such networks of cultural flow that maintain a specific ethnic relationship for the Mixtec, who are indigenous to their region of Mexico and not to Mexico as a whole. Unfortunately, the specificity of this cultural relationship is not acknowledged when subsumed under the term *Latina/o* or by the term *Mexican immigrant*.

Research Issues

Some scholars have begun to argue that socialization patterns differ for ethnic minority populations, reinforcing the importance of ethnic-specific research studies. Research studies that use broad-based terms are subject to misleading interpretations when the culturally specific constructs of one's ethnic background are omitted. In many cases, such studies view Euro-American middle-class families as the norm and frame developmental paradigms to fit this particular group. Conducting research in this manner distorts research findings by failing to acknowledge that European Americans are also part of our racialized society and hence part of a racialized group with a particular social position that grants privileges not accessible by other racialized groups. Thereby, broad-based terms also discount the heterogeneity within European

Americans. These examples illustrate the importance of not dismissing the fact that memberships to social, ethnic, and religious groups are complex and multidimensional, given that groups can be defined by race, gender, age, religion, social class, language, immigrant status, minority status, sexual orientation, and ethnic identification.

Scholars have pointed out that if comparative research studies are planned, it is important to assess them for cultural validity. Cultural validity focuses on the identification of rules that regulate individual and group conduct and the rules that define practices and institutions. Obtaining knowledge of individual and group rules and practices is critical to understanding a particular culture and cultural differences. Through this knowledge, researchers are able to determine the degree to which certain ideas differ in meaning across and within cultures. Incorporating a variety of research methodologies, ranging from focus groups to participant observations in community neighborhoods, family functions, and school settings, will ensure culturally valid assessments.

The interplay between culture and developmental processes is very complex and best captured using a combination of methodologies. Multiple methods of inquiry, assessments, analysis, and interpretation must be employed in order to comprehend the impact of cultural processes on adolescent development. Albeit common, the usage of a certain assessment tool or method of inquiry constructed for one population, yet employed in another population, suggests that one standard is the norm. As discussed, this assessment becomes problematic. Embedded within these methodological issues is the manner in which categories are constructed to define the population or the context being researched. For example, if a concept or object has diverse meanings among individuals of different cultures, then it is challenging to compare data on the concept or object across cultures or assume that the research collected based on these discrepancies is valid and hence advancing our current knowledge. Furthermore, scholars caution researchers to be critical of using the same measure or instrument to assess individuals within a single ethnic or racial group because of the intragroup diversity. It is important to acknowledge that these measures were designed for a particular group and may not have measurement equivalence across or within ethnic groups. Researchers who conduct comparative research studies with culturally different

groups are encouraged to evaluate the degree of interpretive validity.

CURRICULUM DEVELOPMENT

Curriculum development refers to the planning and documenting of a teaching/learning episode, whether it is a short course undertaken at one particular time or a long course of several years, such as a school curriculum. A school syllabus is an obvious example of a curriculum, but a 2-hour presentation or 1-hour dance class also involves consideration of what the learners should learn, what subject matter is suitable, and how that content should be communicated. Curriculum may also refer to all of the learning experiences planned by an institution or system, provided they are formally planned. The planning process is informed by educational psychology by the established information it provides developers about the nature of the learner, the nature of learning, and the nature of teaching. It also offers a challenge for educational psychology to extend existing frontiers in these areas.

This entry traces the technical process of curriculum development from a consideration of the contributing disciplines; the situational analysis or appraisal of the context; the development of the four substantive elements of objectives, content, methods, and evaluation; and the sequence followed among those elements in the process of development. It also considers the naturalistic process, or the complex interactions and negotiations between participants or developers as they search for consensus about a suitable teaching/learning episode.

The Meaning of Curriculum

One beguiling interpretation of the curriculum is to regard it as a personal transaction between a teacher/trainer and learner. Although that is true in one sense, there is also a broader context in which these transactions occur, a context that is part of the economic, political, and social nature of society. So, to understand the curriculum and its development, there is a need to understand the complex nature of society. The curriculum is not separate from society, but embedded in it.

Some definitions of curriculum often implicitly acknowledge this relationship. School curriculum, for instance, is sometimes portrayed as the context in which generations seek to establish self-identity. It is also represented as a reflection of what people in a society think, feel, and do. Other definitions that focus on a system or institution, typically the school, may equate curriculum with a syllabus prescription: an organized set of formal educational experiences, often specified by outcomes to be achieved. Others adopt a broader

interpretation, defining it as all of the learning experiences planned and guided by the school. The definition of curriculum adopted in this article is applicable to both the narrow and broad conceptions.

Decisions informing the process of curriculum design include the contributing disciplines of psychology, philosophy, and sociology; the external and internal factors comprising the situation or context; and the substantive subject matter of the curriculum itself.

The Contributing Disciplines

Knowledge of the contributing or foundation disciplines of psychology, philosophy, and sociology are essential for curriculum development. Of course, the effective developer also needs a strong understanding of people (how they grow, learn, and cope); and society (how learners are influenced by the various groups and cultures that comprise it).

Psychology contributes through its investigation of the thoughts and actions involved in teaching and learning. It not only provides information that assists curriculum development, but also contributes its own methods of investigation. The list of areas in which psychology informs curriculum planning is virtually limitless, and includes the following:

- The nature of learners—how learners react in learning situations.
- The process of thought—how learners select and process information.
- The theories of learning—how learners learn.
- The selection of learning experiences—why particular strategies are suitable for learning. Such decisions necessitate prior consideration of theories of learning, theories of cognitive and affective development, individual differences, motivation, personality, group dynamics, and teaching style.
- The conditions for learning—what constitutes optimal learning conditions (including physical requirements, grouping, and the degree of responsibility given to learners).
- The individual differences among learners—how the differences in learner ability and aptitude affect learning.
- Teacher effectiveness—how the teacher or trainer's teaching style, leadership, interaction with learners, and general behavior influence learning.
- Personality—how different learner "personalities" respond to different learning experiences.

Several psychological theorists have had an enduring impact on curriculum design. Arguably the most influential is Jean Piaget and his four-stage theory (sensori-motor, pre-operational, concrete operations, and formal operations) accounting for intellectual development from birth to adolescence. Other major contributions include the work of David Ausubel, with his general view of learning and classroom practice, and his specific notion of "advanced organizers," or strategies of organization to enhance learning; Benjamin Bloom, with his taxonomy of educational objectives in the cognitive domain; Jerome Bruner, with his models of learning; Robert Gagne, with his hierarchies of capabilities; and Abraham Maslow, with his pyramid of needs fulfillment.

The influence of Burrhus Skinner, with his theory of reinforcement and the resultant shift in emphasis to behaviorism, has been replaced more recently by a critical perspective. The current focus is on the development of critical thinking skills in learners, and the practice of thinking about thinking, and about one's own learning (metacognition). Constructivism is the new learning dynamic. Virtually at the far end of the spectrum from behaviorism, it is predicated on the basis that individual learners construct their own knowledge, rather than having it transmitted by a teacher or trainer.

The constructivist view of educational psychology is producing a revolution in the discipline, resulting in classroom and context-based research, and the development of innovative learning environments.

Sociology has had a strong functionalist influence on the development of curriculum, that is, a view of learners as the products of society, as creations of the process of socialization. This notion, sometimes viewed as an equivalent of the behavioral trend in psychology, prompted investigations of how class, gender, and ethnicity have an impact on curriculum. More recent approaches to sociology are enabling curriculum developers to detect economic, political, and social factors that create preferences for different curriculum practices. Sociology also sheds further light on future trends in society.

Philosophy contributes through the data it provides on epistemology (the nature of knowledge); ethics (the value of knowledge); and the provision of clarity (definitions, priorities, relationships between entities). It underlines the importance of developers and teachers in reflecting upon their own implicit philosophies of education to consider the consequences of this for the practice of curriculum design.

Situational Analysis

Although curriculum development is informed by the contributing disciplines, it does not take place in a vacuum. It is context bound. As curriculum is designed to "fit" the needs of particular systems or institutions, the necessary first step in the process is a situational analysis, sometimes referred to as an "environmental scam," audit, or needs assessment. This examination of the context in which the curriculum is to operate is a systematic process that continues throughout development and implementation to shape the nature of the learning experiences.

The context factors to be considered may be external to the institution or internal. These factors may include the following:

- The people for whom the curriculum is being designed, for example, the experience, cultural background, social skills, and needs of the learners, or in the case of schools, the abilities and the intellectual, emotional, social, and physical development of the learners.
- The people who are implementing the curriculum, for example the interests, expertise, strengths and weaknesses of trainers and/or the teaching style of teachers.
- The resources available to support the curriculum, for example, the equipment, facilities, space, technology, and personnel both within and external to the system or institution.
- The system or institutional requirements, for example, the mandates, system and institutional policies, and existing curricula.
- The nature of professional curricular support, for example, the availability of professional networks, consultant support, and on-the-job professional development.
- The climate, ethos, or atmosphere of the system or institution, for example, the palpable warmth, openness, and harmony, or their opposites.
- The broader societal changes and expectations, for example, the nature of technological, economic, or demographic change, or in the case of schools, the impact of multiculturalism, parent involvement, and changes in family structures.

Curriculum Elements

Whether a curriculum is developed for a day, a short course, or several years, its development requires information regarding four questions that were first posited by Ralph Tyler: What am I trying to achieve? What content will I use to achieve it? How will I organize the content to achieve it? How will I know if I've been effective?

Each of these questions involves a curriculum element or substantive element, or what have been dubbed collectively as the *curriculum commonplaces.* They are objectives/outcomes, content, methods and assessment/evaluation, and when designing curricula, developers are necessarily involved in making decisions about each of them. Following is a brief description of the four curriculum elements.

Objectives/Outcomes

There is a plethora of terms used to describe different degrees of precision in statements of curriculum intent, and the precision denoted is variable across country and context: goal, aim, general aim, specific aim, objective, behavioral objective, expressive objective, process objective, terminal objective, outcome, indicator, and pointer. The question of how precise a statement of intent should be has been a contentious issue from the 1960s, and received impetus with the advent of outcomes-based education in the 1980s and 1990s.

The proponents of using precise outcomes (and outcomes-based education) as a curriculum focus argue that it provides a more explicit indication of what students have to achieve; it diminishes the emphasis on content to be covered and accentuates the skills to be achieved; it enables the assessment of higher-order and more varied outcomes; it eliminates permanent failure (as those who don't initially achieve an outcome may do so in time); and it increases system, institution, and teacher accountability. Conversely, the detractors argue that outcomes-based education is narrow, mechanistic, and behaviorist; it constrains inquiry and creativity; it devalues the affective dimension; and it trivializes knowledge with the assumption that all learning can be broken down into outcomes.

The time-honored framework still used in schools as a guide for curriculum planning was created by Benjamin Bloom, who developed taxonomies of educational objectives in the cognitive and affective domains, respectively.

Content

The detailing of curriculum content may simply involve the identification of relevant topics, although

a curriculum of significant duration may involve the initial development of a conceptual framework, that is, a "cognitive map" displaying the relationships among the content parts (facts, ideas, skills). Frameworks may comprise subtyping, aggregation, and the relationship between entities, and are a first step in the full detailing of content. In curricula involving the development of skills, an equivalent first step is a task analysis (a breaking down of skills into more finite parts).

Methods

The methods or teaching/learning strategies are the means of acting upon the content and might include explanation, narration, demonstration, questioning, brainstorming, problem solving, role-plays, moral dilemmas, graphic organizers, values clarification, and simulations. They might also involve the structures for organizing students (working independently or using snowball or jigsaw groups). Appropriate methods are generally selected according to learning theory and other established educational principles, for example, the need for learning to be active; enable reinforcement and transfer; consider the culture and values of the learner; involve real-world tasks, informal choices, and even risk-taking; and promote the refinement of initial attempts. Benjamin Bloom's taxonomy is also used as a strategy to impart content in schools.

Assessment/Evaluation

Assessment answers Tyler's fourth question: How will I know if I've been effective? In outcomes-based education regimes, planning for assessment involves determining the extent to which outcomes have been achieved. Once regarded as occurring at the end of a course, assessment is increasingly viewed as a continuous and integral part of teaching and learning. It is also used to provide regular feedback to learners and to indicate their progress toward outcomes. The information obtained is used to inform the nature of teaching.

The debate on assessment strategies in schools remains contentious and involves the relative merits of testing (multiple-choice, true-false, short answer, matching, cloze, interpretive tests, and essays) and performance assessment (checklists, rating scales, anecdotal records, and portfolios). Some commonly accepted principles include the need for assessment to identify strengths and weaknesses, use a range of strategies, refer to explicit criteria, and provide more than one opportunity for learners to meet requirements. Arguably more contentious principles include opportunities for learner self-assessment, negotiation of required tasks, and collaboration among learners.

The mere identification of the four substantive elements does not provide information on the process of curriculum development. There are two broad types of models for developing curricula: the technical or systematic models based on a sequence (fixed or flexible) of the substantive elements of objectives, content, methods, and evaluation; and the naturalistic models based on the interactions and negotiations surrounding questions of who makes curriculum decisions and how.

Technical Models

The most common model in the field of curriculum development is Tyler's objectives model, sometimes also called the means-end model. The four questions previously posed by Tyler, from which the substantive elements are derived, are seen to provide a logical sequence of development, viz objectives, content, method, and evaluation. The first step in the model is the stating of objectives. The source of these objectives includes what students need to know and what society believes should be taught. No single source is adequate, although Ralph Tyler refers to psychological and philosophical principles as "screens" to determine the more important objectives.

The second and third steps involve the selection and organization of learning experiences. These are the means of achieving the ends or objectives. The final step of evaluation involves determining to what extent the objectives are achieved through the selected content and method.

The model has its supporters and detractors. The supporters argue three generic benefits:

1. By providing objectives as the essential first step, the model provides a clear direction for the remainder of the process. Advocates have often presented the metaphor of a journey: How often do you get into your car without knowing where you are going? An objective is equivalent to a destination.

2. The model provides a blueprint to simplify the process. The fixed sequence is regarded as a helpful structure, particularly for those who are new to the task of curriculum design.

3. The model does possess at least a prima facie logic, that is, the specification of the ends to be achieved (the objectives), followed by the means of achieving those ends (content and method).

Common criticisms of the model include the following:

- Curriculum development in practice is rarely a fixed or linear sequence. It is more typically a chaotic and idiosyncratic process with movement to and fro among the elements. Such a criticism may well be countered by the claim that typical practice is not necessarily ideal practice.
- The model does not adequately explain from where the objectives come.
- The structure of knowledge is such that it cannot be expressed in terms of prespecified performance. Theorists including Lawrence Stenhouse claim that it is possible to select content irrespective of its instrumental value in achieving ends or objectives. He argues that each form of knowledge possesses its own structure and therefore requires a distinctive methodological approach to acquiring it. This process approach acknowledges the inherent worth of certain content and accents those procedures that are appropriate for discerning the knowledge implicit in that content.
- The model risks an overemphasis on measurable objectives. Many objectives, particularly those in the affective domain, are less amenable to quantitative assessment and therefore could be ignored.

Although the objectives model is the traditional model, it is not merely a relic. The relatively recent push for outcomes-based education may well have rejuvenated an objectives model in which outcomes are substituted for objectives.

The interaction or dynamic model indicates a different relationship among the curriculum elements. Curriculum development is regarded as a dynamic process that can begin with any curriculum element and follow any sequence among them. Instead of the elements following a fixed sequence, they are regarded as interactive and progressively modifiable (a change to one element will necessitate changes to the other elements). For example, the addition of content may involve changes to objectives, methods, and evaluation.

The claimed strengths and weaknesses are not as well documented as those of the objectives model, but supporters cite the strengths in terms of the characteristics—the model is psychologically efficient and flexible in enabling the developer to begin with any one of the elements, follow any sequence, and move to and fro among them. The lack of being constrained by a fixed process is regarded as a truer reflection of the reality of curriculum development.

Proponents of the objectives model believe that not specifying objectives as the starting point may result in their being accommodated to the content specification and thereby be contrived and decorative. They also argue that if the model is not systematic, that is, has no fixed sequence, the constant changes of direction might be reflected in a piecemeal finished product or curriculum.

Naturalistic Models

Only relatively recently has the curriculum development literature moved beyond a consideration of the substantive elements to an examination of the complex interactions, negotiations, and compromises surrounding questions of who makes curriculum decisions and how. One such early model is that of Decker Walker, who coined the term *naturalistic* to portray how curriculum planning actually occurs. His three-step sequence of platform, deliberation, and design is a reflection of observed practice.

The term *platform* refers to the shared principles that evolve from the discussion of participants about their various values, beliefs, perceptions, and commitments. For Walker, this suggests both a political platform and something to stand on, and includes an idea of what is and a vision of what ought to be. A platform might comprise conceptions (beliefs about what exists), theories (beliefs about relations between existing entities), aims (beliefs about what is desirable), images (less well-formulated notions that a change is desirable yet with no clear indication of what), and procedures (vague indications of proposed action with no clear specification of why they are desirable).

Deliberation involves the ways in which beliefs may be used to identify problems with the existing curriculum, and how new curricula may eliminate these problems. So, deliberation comprises interaction and argument in debating alternative perceptions and solutions. It may involve the expression of feeling and frustration as developers express their different ideas of what should be done. Walker describes the process as chaotic and confused.

Design begins once deliberation has made explicit what has to be done, that is, when the participants have achieved consensus about beliefs and viable solutions.

The model accents the need for meaningful debate and the sharing of beliefs, feelings, and perceptions. It also allows for the confrontation of conflicts (the stimulus for change). One prima facie criticism is that the model may be more applicable to large-scale curriculum design involving many participants, and for which deliberation is a prerequisite, as opposed to curriculum change for which consensus is assumed and that involves routine tasks.

There is possibly also a danger in viewing curriculum development as the reconciling of conflicting and competing interests, rather than promoting the perception of a core of common interests. Such a view does not diminish the importance of difference or conflict. The latter is regarded as a prime factor in promoting quality curriculum development as it causes decisions to be determined more thoughtfully; stimulates creativity by exposing different views or solutions; increases psychological intensity, physical energy, and curiosity; produces awareness of problem areas in relationships; and enhances self-knowledge. Democratic societies celebrate difference and productive conflict, but a key to understanding the curriculum is to discern common interests that unite people.

Stakeholders

Achieving consensus may be more difficult if the stakeholders, or those who have an interest in the likely impact of the curriculum, come from a broad spectrum of society. Arguably, the values and views of participants may be more homogeneous in a single, small institution in which the services are directed toward a well-defined goal. Conversely, there are individual and group interests in school curricula that are both internal and external:

- Parents have personal, social, and often vocational aspirations for their children, and they invest their faith in the school and its curriculum to ensure that this happens.
- Teachers are disposed toward the academic rather than the vocational, and possibly the theoretical rather than the practical. Their task is to interpret system guidelines and to add a pedagogical dimension that creates ongoing curriculum experiences for students.
- Community groups, notably social services agencies dealing with social, medical, and welfare issues related to young people and their families, have a stake in school curriculum. As students have lives outside classrooms, their external environment is a powerful influence on attitudes and behavior, and the school curriculum is a potentially powerful force in developing appropriate behaviors. In most countries, groups of individuals have special interests that school curricula must also address. Such interests may include indigenous groups, people with disabilities, people from a non-English-speaking background, people who live in poverty, and the geographically isolated.
- Governments have interests that are largely, although not exclusively, economic. The nature of the school curriculum will determine the knowledge and skills that future citizens will possess and hence their capacity to contribute to the nation's economy. Of course, democratic governments also desire a community that is socially cohesive, politically literate, culturally sophisticated, and just.
- Businesses share the government's economic interest. They need workers who are both skilled in particular areas and also literate and numerate.
- Universities and agencies of further education have a strong interest in the nature of the school curriculum, and often play a watchdog role to ensure that potential students are well equipped to undertake further study.

If the school curriculum is perceived as a means by which students become responsible and productive citizens, then virtually everyone has a stake in the nature and development of the curriculum.

The price of the democratic way of life is a growing appreciation of people's differences, not merely as tolerable, but as the essence of a rich and rewarding human experience.

—Jerome Nathanson

Deductive Reasoning

Psychological investigations of deductive reasoning focus on inferences drawn from premises conveying operators such as *if*, *and*, *or*, and *not*, and quantifier terms such as *all* and *some*. Formal logic typically is used to determine which deductive inferences are valid. People routinely draw many valid inferences, but often accept others that are fallacious, and psychological research needs to account for both. Some researchers, such as Jonathan Evans, have focused on task features that influence fallacious inferences, proposing biases and heuristics in reasoning. This approach, however, does not explain the valid inferences that people make, nor the intuitions about the validity of such inferences.

Researchers such as Patricia Cheng, Keith Holyoak, and Leda Cosmides have focused on the role of content in making inferences, and certain types of content can both discourage some common fallacies and encourage some valid inferences. This approach, however, does not explain a wide set of valid inferences made with content outside of those described in these theories. Other researchers, such as David Over, Mike Oaksford, and Nick Chater, have proposed Bayesian inferential processes, in which knowledge about problem content

guides computations about probabilities. These theories do not explain inferences that are made from premises with abstract content.

Two research paradigms address deductive inferences across all sorts of content: mental-logic theories and mental-models theories. Two mental-logic theories have been proposed, one by Lance Rips and another by Martin Braine and David O'Brien. These theories propose sets of inference schemas and procedures for implementing the schemas. Many reasoning errors are explained by limitations in the reasoning procedures. Braine and O'Brien proposed a universally available direct-reasoning routine that applies the inference schemas whenever the requisite propositions are considered simultaneously. For example, when premises of the form *p or q* and *not p* are in working memory conjointly, a schema infers *q*, and when premises of the form *if p then q* and *p* are considered conjointly, another schema infers *q*. Considerable evidence shows that people apply such schemas automatically and effortlessly whenever the premise information is available both in laboratory problems and in stories. Reasoning strategies that go beyond the basic program are not universal and require effort, and problems that require such strategies are solved far less and often lead to fallacious inferences. Another source of reasoning error addressed by the mental-logic approach is found in pragmatic inferences. For

example, *if p then q* can invite one to infer *if not p then not q*, which is not deductively valid.

Philip Johnson-Laird and Ruth Byrne have proposed a mental-models theory in which people construct analogical representations of premise information. Because working memory has limited capacity, people tend to construct only minimal representations, although a completely logical representation usually would require more complete models. For example, given the premises *if p then q* and *p*, one can construct the following incomplete models:

$$p \quad q; \quad p; \quad p \quad q$$

where the models for the two premises and then for their combination are separated by semicolons. A conclusion will be based on the final model, which would support a conclusion of *p and q*, although no one states this conclusion, saying instead only *q*. Models theorists explain this by arguing that because *p* is a categorical premise, its inclusion in a conclusion would violate pragmatic constraints.

Models theory explains reasoning errors principally in terms of the number of models required to support a conclusion. For example, given *if p then q* and *q* as premises, one is likely to form these models:

$$p\,q; \quad q; \quad p \quad q$$

which support the fallacious inference of *p* that people often endorse. The inference could be withheld, however, if people "fleshed out" the models to include all possibilities, but this would tax working memory, so people tend to endorse the fallacious inference based on the incomplete models.

Mental-models theory has an advantage in that it promises to provide a general theory of reasoning, that is, being applicable not only to deductive reasoning, but also to all areas of reasoning. The mental-logic approach makes no such sweeping claim and is limited to providing an account of how logical inferences are made for propositional operators such as conjunctions, alternatives, negations, and suppositions, and for various quantifiers. Mental-logic theory, however, has the advantage of making specific predictions that are supported by the data, whereas mental-models theory leads to some problematic predictions. For example, consider the premises mentioned above, *if p then q* and *p*, which in models theory would lead to the conclusion *p and q* except that *p* is not included in the stated conclusion because of pragmatics. It

follows that a similar problem with the same premises but with *not both p and q* as a conclusion should lead to a straightforward evaluation of "false" because *p* and *q* are in the final model. People, however, make an intermediate inference of *p* before saying "false," which models theory cannot explain. (The intermediate inference is explained by mental-logic theory.) Of course, the two theories are not exclusive, and one need not choose one over the other. A skilled thinker would benefit from using both sorts of procedures.

Descriptive Statistics

Descriptive statistics constitute a branch of statistics that provides a variety of techniques used to present a quantitative summary of a given set of data. In contrast to descriptive statistics are inferential statistics, which provide ways to make inferences about the population from which the data were sampled.

When summarizing data on a single variable is of interest, there are at least two major characteristics to be considered: central tendency and dispersion. These

characteristics represent some aspects of the distribution of the data. The *central tendency* denotes where the center of the data distribution is located. The *mean*, the *median*, and the *mode* are commonly used to describe the central tendency. The mean is the average of all data values, that is, the sum of data values divided by the number of observations. The median is the midpoint in a set of sorted data values; half of the data values fall above the median and half of the data values fall below it. The mode is the data value that appears most frequently in the given set of data.

The *dispersion* refers to the degree to which the data vary around the center of the distribution, or to what extent the data are spread out. One of the measures of dispersion is the *standard deviation*, which indicates the extent to which individual data points depart from the mean on average. Technically, it is defined by the following formula:

$$s = \sqrt{\frac{\sum_{i=1}^{N} (X_i - \bar{X})^2}{N}},$$

where X_i is the ith observation, $\bar{X}$ is the mean, and N is the total number of observations.

Another term for dispersion is variation. A measure for data variation is variance, which is defined as the square of the standard deviation. To illustrate how these indices are used, a set of data will be analyzed.

Example 1

Suppose that 20 children took a math test and we observed the following scores:

$$6, 12, 11, 14, 11, 13, 14, 11, 11, 7, 8, 10,$$
$$12, 15, 7, 8, 12, 16, 5, 11$$

The mean for the above data is 10.70. If the above data are sorted, scores for the 10th and 11th observations are both 11. The median is their average (because the total number of observations is an even number), and thus calculated as 11. The mode for the above data is 11, because the score 11 is observed most frequently (five times). When the data distribution has a single mode and is almost symmetric about its center, as in this example, these three measures give almost the same values. When the distribution is skewed or when there are a few extreme values (outliers) in the data, the three measures of central tendency can disagree.

Although the mean is most commonly used because of its computational and interpretational convenience, the median or the mode is preferred for skewed data or when outliers are present, because the mean is sensitive to these factors and could be misleading as a representative value of the distribution. The standard deviation is calculated as 3.05 for the above data and the variance is thus 9.30. It should be noted that the standard deviation, like the mean, may not be representative of data if the distribution is highly skewed (i.e., lacks symmetry), because the average dispersion can differ for the data points above the mean and for those below the mean (and the mean itself is also affected by the skewness).

Quantiles such as *percentiles* and *quartiles* are also useful in describing a data distribution. Let the data be sorted in an ascending order. Divide the sorted data into 100 subsets of equal size. The kth percentile is defined as the boundary value between the kth subset and $(k+1)$th subset. The interpretation of the kth percentile is that $k\%$ of the observations in the data fall below the kth percentile. The zero percentile corresponds to the smallest value in the data, and the 100th percentile to the largest value. Quartiles are defined in the same manner, but the data are divided into four subsets. Thus, the first, second, and third quartiles correspond to the 25th, 50th, and 75th percentiles, respectively. The median is equivalent to the 50th percentile or the second quartile.

For the data in Example 1, the first, second, and third quartiles are 8, 11, and 12.25, respectively, indicating that half of the scores are between 8 and 12.25 and that the data distribution is somewhat skewed to the left, because the distance between the first and second quartiles is longer than the distance between the second and the third. The *interquartile range* is defined as the difference between the third and the first quartiles, and it is used as a measure of dispersion. In the above case, the interquartile range is 4.25.

When two or more variables are summarized at the same time, one may be interested in describing relationships between those variables as well as univariate summaries of individual variables. The *correlation* is one of the most commonly used measures of a relationship between two variables. The correlation between two variables X and Y is defined by the following formula:

$$r = \frac{\sum_{i=1}^{N} (X_i - \bar{X})(Y_i - \bar{Y})/N}{\sqrt{\sum_{i=1}^{N} (X_i - \bar{X})^2/N} \sqrt{\sum_{i=1}^{N} (Y_i - \bar{Y})^2/N}}.$$

The numerator in the above formula is called the *covariance*, and the denominator is the product of standard deviations. The correlation measures the strength of a linear relationship between two variables. A correlation of 1.0 (or –1.0) indicates the perfect positive (or negative) linear relationship (i.e., all data points lie on a single line in a two-dimensional plot). A zero correlation implies that there is no linear relationship between two variables.

Example 2

Suppose that you have scores of a reading test from the same 20 children as in Example 1:

6, 14, 14, 9, 7, 18, 10, 9, 10, 9, 10, 9, 15, 15,

10, 9, 13, 12, 11, 12

The standard deviation of these scores is 2.99. The covariance between math and reading test scores is 4.40, resulting in the correlation .48. Thus, reading and math test scores are positively correlated.

Graphical and tabular representations are other ways to present summaries of data. For example, a data distribution of a single variable can be visualized by a *histogram.* A *frequency table* may be often used to summarize categorical data. A relationship between two variables is made visible by drawing a *scatterplot.* These representational tools complement the various descriptive statistics that may serve as aides to understand data in more detail.

DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS

The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) is a comprehensive summary of all known forms of psychopathology. It is published by the American Psychiatric Association and is currently in its fourth edition (*DSM–IV*). The *DSM* is used by both researchers and clinicians to identify psychological disorders.

History

The need for statistical information was the initial impetus in the United States to develop a classification system of mental disorders. The first official attempt was the recording of the frequency of one category labeled "idiocy/insanity" in the 1840 census. By the 1880 census, seven categories of mental illness were distinguished—dementia, dipsomania, epilepsy, mania, melancholia, monomania, and paresis. In 1952, the American Psychiatric Association Committee on Nomenclature and Statistics published the first edition of the *DSM*. This edition and the one that followed were based on a psychodynamic interpretation of each diagnosis. Beginning with the third edition, the *DSM* has used an atheoretical approach to diagnosis, which has increased the reliability between raters for establishing diagnoses.

Use of the *DSM*

The *DSM* consists of a multiaxial classification system used by clinicians to diagnose individuals, plan treatment interventions, and predict probable outcomes. Diagnoses are established along the following five axes:

Axis I: Clinical Disorders and Other Conditions That May Be a Focus of Clinical Attention

Axis II: Personality Disorders and Mental Retardation

Axis III: General Medical Conditions

Axis IV: Psychosocial and Environmental Problems (rated with descriptive categories)

Axis V: Global Assessment of Functioning (rated from 1 [persistent danger to self or others] to 100 [superior functioning to a wide range of activities])

All mental disorders/conditions listed in the *DSM* fall under Axis I with the exception of Personality Disorders and Mental Retardation (listed under Axis II). Mental disorders or conditions that are the main focus of clinical attention are usually listed on Axis I. This axis is composed of the following categories: schizophrenia and other psychotic disorders, mood disorders,

anxiety disorders, somatoform disorders, disorders usually first diagnosed in childhood (e.g., autistic disorder), eating disorders, delirium, dementia, amnestic and other cognitive disorders, sleep disorders, impulse control disorders, and adjustment disorders.

Axis II is used for reporting personality disorders as well as mental retardation. Listing these conditions on a separate axis emphasizes the chronic and inflexible nature of this class of disorders. The personality disorders are classified into three broad clusters, as follows: cluster A, odd and eccentric (paranoid, schizoid, and schizotypal); cluster B, expressive/labile (antisocial, borderline, histrionic, and narcissistic); and cluster C, anxious (avoidant, dependent, and obsessive-compulsive).

General medical conditions that may be pertinent to the understanding and/or treatment of an individual's mental condition are reported on Axis III. For example, persons with severe forms of arthritis are more likely to be depressed due to the pain and physical limitations associated with their medical condition.

Axis IV accounts for environmental or psychosocial factors that may potentially limit the effectiveness of the treatment for disorders on the first three axes. For example, the loss of job and the financial issues associated with that loss would complicate treatment of depression. There is a broad range of possibilities that could be listed under this category. The clinician should list the category as well as specifics about the problem. The main categories with some examples are as follows: problems with primary support group (e.g., divorce, neglect of child, health problems among family members); problems related to the social environment (e.g., death of a friend, discrimination, adjustment to retirement); educational problems (illiteracy, academic problems); occupational problems (unemployment, stressful work environment, discord with a co-worker or boss); housing problems (homelessness, unsafe neighborhood); economic problems (poverty, inadequate finances); problems with access to health care (lack of transportation to health care services, inadequate or lack of health insurance); problems related to interaction with the legal system/crime (incarceration, litigation, victim of crime); other psychosocial and environmental problems (exposure to disaster, discord with nonfamily caregivers such as counselor, social worker, or physician).

Axis V is used by the clinician to give an overall picture of the client or patient's level of functioning in recent and current everyday living. Thus, this axis is rated for the highest level estimated for the year prior to the assessment as well as the functioning level at the time of the diagnosis. The rating for the highest level of functioning in the previous year often helps the clinician provide a prognosis. The scale to make the ratings is the Global Assessment of Functioning Scale (GAF), which is divided into 10 ranges of functioning from 0–100 (0–10; 11–20; 21–30; 31–40; 41–50; etc.). The clinician considers psychological, occupational, and social functioning to assign the patient a particular number within the 0–100 range that coincides with a description with that particular number range. For example, a patient's GAF score of 70 would represent "mild symptoms (e.g., depressed mood or mild insomnia) *or* some difficulty in social, occupational, or school functioning (e.g., occasional truancy, or theft within the household) but generally functioning pretty well, has some meaningful interpersonal relationships" (American Psychiatric Association, p. 34).

Importance

The overall purpose of the multiaxial format of the *DSM* is to provide a comprehensive and organized system for categorizing various types of psychopathology. This system allows different professionals (e.g., psychologists, physicians, social workers) to communicate effectively regarding a patient's mental disorder and associated conditions. It also provides information to third-party payers.

DIRECT INSTRUCTION

Direct instruction has at least two meanings. The first meaning refers to the generic behavioral features of explicit teaching in which teachers demonstrate a performance, guide students as they attempt to perform, and continue student/teacher exchanges until students can perform without further guidance. Barak Rosenshine and others have described these features in detail. Thomas Gilbert developed a classic direct instruction model, which he called *Mathetics*, a Greek word meaning "to learn." Teachers who implement direct instruction methods are usually teaching well-defined learning objectives; for example, simple associations such as the table of elements in chemistry; sequences such as the long division algorithm; concepts such as kinds of trees or modern art styles; and applications of principles such as supply and demand in economics, rules of punctuation, detecting an author's purpose, or inferring more information about characters and settings in literature. Direct Instruction teachers are usually aiming for student mastery of objectives. This entry refers to these generic features of instructional delivery as *direct instruction*, with lower-case letters to begin each word.

A second meaning of *Direct Instruction* refers to a theory of instruction developed by Siegfried Engelmann, specific programs designed from his theory, and specific direct instruction delivery techniques espoused by his theory and programs. The first letter in each word, *Direct Instruction*, is capitalized when referring to Engelmann's theory, programs, and methods. Direct Instruction is often abbreviated as DI, with the two letter-names pronounced when referring to it.

First, this entry describes features of generic direct instruction presentation methods, and then describes Engelmann's Direct Instruction.

Presentation Methods

A direct instruction lesson is an exchange between a teacher and either a single learner, a small group of learners, or an entire class. Students engage with a teacher in highly interactive lessons that introduce one performance or skill at a time and cumulatively combine them as accuracy emerges. Establishing new performances with direct instruction is equivalent to generalized imitation training. Teachers *demonstrate* and *model* expected performance, *lead* and *prompt* students through the performance, and then *release* or *test* the students' performance. These steps in the process are easily identified during instruction when teachers preface by saying "My turn" when they demonstrate and model, "Our turn" when they help the learners to perform accurately, and "Now your turn" when they check to see whether students can perform without assistance.

Many learners need a very explicit and structured version of direct instruction to make rapid progress. They also need a curriculum that has been more carefully designed than the average textbook presents or the average teacher outlines in a lesson plan. These include (a) young learners, (b) older learners with deficient learning skills, (c) learners with learning and developmental disabilities, (d) learners at a cultural disadvantage in academic learning, and (e) learners who encounter brand-new content that allows for little transfer of training. For these learners, Engelmann's Direct Instruction (DI) curriculum, as well as his direct instruction procedures for delivering instruction, are very effective. His direct instruction procedures are examined first, and then his Direct Instruction (DI) program design.

Teachers present to learners DI lessons that designers have scripted, word for word, in advance. The scripts take the utmost care to present a hierarchy of component and cumulative compound skills. The best DI scripts have been "learner verified"; that is, tested with hundreds of learners in many settings and revised until they work. During a DI lesson, learners answer teacher-initiated questions and tasks in unison. Teachers move through a series of questions and tasks in a predictable manner, provide attending cues to ensure that all learners are focused on the task, and signal learners to ensure that they respond together. Teachers may use a variety of signals—for example, tapping a pen on an overhead transparency or snapping their fingers—until they find one that works, is comfortable to use, and doesn't distract students. Teachers systematically vary the latency between the question and the response signal to ensure that the signal tightly controls responding.

Teacher and students volley many times a minute with their questions and answers. Teachers praise and correct student responses, providing parallel tasks until all students are accurate. The explicitness and careful progression of Direct Instruction lessons ensures that at-risk students develop flawless skills very quickly.

With DI lessons, not only do low-skilled learners master the skills and concepts, but also inexperienced teachers learn to establish new performances. In the process of using DI scripts—which tell the teacher exactly what to say, how the learner should respond, how to predict errors, and how to provide error correction procedures—teachers are explicitly shaped to establish skills.

The challenge for the inexperienced Direct Instruction teacher is to faithfully present the lesson as designed. This requires achieving choral responding among learners, listening carefully to the quality of their responses, providing encouraging feedback following correct responses, and applying specific error correction procedures that effectively reduce errors. They must proceed at a pace that provides optimal thinking time before students respond. The pace must be gradually increased to squeeze out most thinking time as skills reach mastery. Teachers must keep track of the three delivery phases (demonstrate, prompt, and test) and engage in them recursively. For example, teachers may demonstrate a skill a few times, then try an "our turn" exchange. If it flops, then the teacher must return to the demonstration phase. Likewise, "your turn" attempts may fail, at which point the teacher must return to "our turns." Teachers must also provide individual turns to students, to make sure that they did not miss errors during choral responding. Even though teachers may consult the script during the lesson, they must be conversant enough with its pattern to maintain eye and ear contact with learners. The best results occur when teachers are able to implement programs with a great deal of procedural reliability, although the lessons are generally forgiving about small lapses in procedure.

Direct Instruction Program Design

Engelmann describes seven criteria for Direct Instruction program design. First, average to below-average teachers should be able to teach a program successfully after receiving a week or less of training with some follow-up, in-classroom coaching. Second, teachers, principals, and other instructional leaders should be able to reliably predict the amount of student progress a program will produce in a given time period. At least three features of Direct Instruction programs allow for such reliable predictions. Because students are homogeneously grouped for instruction, the teacher can focus on teaching the same content to all students. Homogeneous grouping makes the instructional agenda very clear and has remarkable data supporting it independent of DI. Given a clear agenda, the lessons in a program should be scripted to give teachers the clearest and most consistent language for teaching the material, as determined in empirical tryout and revision of the scripted lessons, and to keep teaching focused on the content to be mastered and not extraneous but related matter. Scripts include many examples of a learning objective, as well as close-in nonexamples ("almost like but not quite") to teach the *general case* of a concept, skill, or principle. The lessons in a Direct Instruction program also have a specified time during which students are expected to master the content, typically 30 to 40 minutes in length. Research indicates that high performers typically master about 1.3 lessons per day, middle groups about 1 lesson a day, and lower groups about .7 lessons per day.

The third criterion for Direct Instruction program design is that the sum of the skills and concepts to be taught is substantially greater than the sum of the skills the students currently master. Inspection of DI programs may indicate less variety of activities or topics when compared to traditional materials, but there is usually no evidence that the traditional materials actually teach the content they purport to teach. The empirical nature of the design, tryout, and revision process of Direct Instruction programs promotes mastery.

Fourth, Engelmann's Direct Instruction programs are based on a theory of instruction, which is beyond the scope of this entry. Suffice it to say, his logical analysis of knowledge, analysis of teacher–student communication, and functional analysis of student behavior has produced many effective programs. Empirical evidence shows that the lesson presentations are consistent with one, and only one, interpretation.

The fifth criterion for Direct Instruction program design is that interactivity must be built into the lessons to guide the teacher in adjusting the rate and type of presentation students need at each moment. Because of the high frequency of teacher–student exchanges, teachers know when to engage in each of the three direct instruction delivery phases (i.e., provide more demonstration, provide prompts to guide the students, and provide student tests). A DI program should also include periodic cumulative, curriculum-based tests.

The sixth criterion is the long view that a curriculum sequence takes, anticipating the prerequisites for

later, more complex learning. A program must fully prepare the student early and systematically with skills and concepts that will guarantee the student learns later, more complex content. This focus on prerequisite skills promotes teaching priority skills over trivial skills. The seventh criterion states that a Direct Instruction program should provide consumer protection information to suggest that successful outcomes are possible. The thorough field testing that each Direct Instruction program receives virtually guarantees that teachers will teach successfully and students will learn to mastery.

Engelmann and his colleagues have published more than 50 Direct Instruction programs, all classroom-tested and revised with thousands of students until they work. Examples include *Reading Mastery, Corrective Reading, Language for Learning, Language for Thinking, Expressive Writing, Spelling Mastery, and Connecting Math Concepts*. These programs are available through SRA/McGraw-Hill.

Direct Instruction Evaluation

The U.S. Department of Education first documented the effectiveness of Direct Instruction in the 1960s. They sponsored Project Follow Through ("following through" on the preschool Head Start programs). Anyone with an educational model for teaching disadvantaged students in grades K–3 was invited to enter a comparative evaluation; 13 different educational models participated. Twenty-one community sites selected the Direct Instruction model. The Direct Instruction students outperformed students in all other Follow Through models including Open Education, Behavior Analysis, Bank Street, Cognitive Curriculum, and Parent Education. The DI students showed superior progress in reading, arithmetic, spelling, and language. Direct Instruction students also had the most positive self-image of any students.

Since Project Follow Through, 151 studies have compared Direct Instruction to another teaching method, the largest number of studies done on any method of teaching in the history of educational research. One hundred and nine, or 64% of the studies, statistically favored Direct Instruction. Fifty-nine, or 35% of the studies, showed no difference, and only two, or 1%, favored a non–Direct Instruction method. A meta-analysis of Direct Instruction studies revealed an effect size of .97, rare in educational research. It is also remarkable that these studies involved a full range of student populations—preschoolers; elementary and secondary students; regular and special education students; adults; and various minority populations, including non-English speakers. No other instructional method that we know has produced more favorable results than Direct Instruction.

Direct Instruction Revisited

The importance of tighter, DI-scripted lessons for at-risk learners of all kinds, as well as for inexperienced teachers, has been discussed. When students are average to above-average learners, and teachers have direct instruction experiences, generic direct instruction lessons to establish performances may be successful. At least half or more learners have more advanced learning-to-learn skills than their at-risk peers. Most courses of study are not brand-new experiences for a learner, although some foreign language and science courses are examples of exceptions. Teachers often reach the point in training and practice where they have fluent generalized repertoires of effective instructional approaches. Instructional lessons for these students and with these teachers allow a shift to more generic direct instruction approaches as described by Gilbert, Rosenshine, and others.

Generic direct instruction lessons still involve frequent exchanges between teacher and students, with praise and error corrections. They also contain model, prompt, and test modulations until all students can perform successfully without assistance. However, students may encounter more teacher talk before responding, with the teacher thinking aloud to show how he or she formulates a successful answer to a task. For example, to teach a reading comprehension skill "making an inference," the teacher may define *inference*, read a short passage, and "think aloud" one or more inferences that can be drawn from the passage. Learner responses to tasks may also require lengthier answers. The teacher may read another short passage and ask students to make inferences and justify their answers. Unison responding may not be choral; teachers may give "think time" to students to write answers to such tasks, and then call on a student or two to read their answers, while others check their answers against the feedback the teacher provides. Students may also compare their written answers in peer pairs. The teacher may back up and provide more think-aloud models if the students are off-base. The teacher may provide hints and otherwise lead

students to make more plausible inferences, and then read a new short passage and test the student's skill at making inferences. Many variations are possible. Mastery is still the learner's goal, and learner performance still drives the teaching, but the learner is expected to reach mastery with less explicit teacher shaping.

DISABILITIES

In the 2003–2004 school year, the federal government reported that more than 6.6 million youth with disabilities were served by federally funded programs in public schools. These youth include individuals with learning disabilities, speech/language impairments, developmental and intellectual disabilities, emotional disturbance, hearing impairments, orthopedic impairments, other health impairments, visual impairments, deafness, blindness, autism, traumatic brain injury, developmental delay, and multiple disabilities. This entry discusses perspectives on disability and the intersection of disability and educational contexts, including pertinent legislation and issues related to the diagnosis and education of youth with disabilities.

Perspectives on Disability

Disability has been conceptualized in terms of type, function, and social construction. Most commonly, perhaps, disability has been construed as a type of limitation with particular characteristics. The four major types are: (1) physical (e.g., spinal cord injury, polio); (2) sensory (e.g., deafness, blindness); (3) cognitive (e.g., learning disability, intellectual disability); and (4) emotional (e.g., schizophrenia, bipolar disorder). A full typology would indicate causes, characteristics, courses, and outcomes for each type of disability and would help to identify the kind of disability one has. Although the medical profession and others have found this approach a useful way to organize knowledge about disability, typologies have not always been able to live up to their promise of providing such information, nor have they always been able to capture the range and kind of disabilities human beings experience.

A second approach is functional. Here the goal is to specify the actual impairments the disabling condition imposes. For example, the Americans with Disabilities Act includes a definition of disability as a condition that results in an individual being unable to perform basic life functions independently, such as walking and bathing. This approach is valuable for specifying the nature and threshold level of impairment involved with the disability. The U.S. legal system sometimes uses a functional approach to identify individuals with disabilities who qualify for protection and benefits under a particular law or policy without regard to whether the exact type of disability they may have is well defined or understood.

The socially constructed approach recognizes the role of society in defining disability. A basic principle is that a disability is defined as an individual's inability to perform in some socially valued way. Thus, if a society values intellectual work, then an individual who cannot learn to read may be considered to have some kind of a cognitive disability. However, in an agrarian society, if most of the population is not able to read, then cognitive disabilities may not be considered important. In fact, many less severe disabilities considered high incidence today, such as learning disabilities, were not recognized as disabilities prior to the Industrial Revolution and its attendant urbanization. A second basic principle of the socially constructed approach addresses the important role of societal attitudes in shaping the nature of the

disability experience. In different societies, attitudes toward disabilities and the persons who have them may be negative, neutral, and/or positive. For example, in some African cultures, an individual who is hallucinating may be considered to be divinely inspired and capable of special healing. In contrast, in mainstream U.S. culture, such a person may be considered to be in need of medication and perhaps hospitalization to treat serious mental illness. More generally, people with disabilities may report that in the eyes of others, their disability overshadows their abilities. Consequently, the attitudes of others toward people with disabilities may constitute a greater difficulty than any impairments resulting from their disability per se.

In schools and other educational contexts, all three of these approaches to defining disability are salient. The attitudes of society, as represented by the perspectives of principals, teachers, and student peers, shape the education of students with disabilities. Where these attitudes are positive, students with disabilities may be more welcomed and fully included in the academic, extracurricular, and social life of the school. In these schools, research suggests that students with disabilities are often more likely to develop positively and perform well socially, psychologically, and academically. Because of the information age in which we live, education is considered an essential opportunity in U.S. society. Therefore, disabilities that affect one's education are socially constructed to be of great importance. Consequently, there are laws protecting the educational opportunity of students with disabilities and professionals to diagnose these disabilities and support affected students and their families. School psychologists and other professionals emphasize both the type of disability and function when they diagnose students to ascertain their eligibility for special education services and determine the intervention and support likely to be most helpful for students with disabilities and their family members.

History of Educational Practices and Legislation

The educational rights of and opportunities for youth with disabilities have changed substantially over time. Early practices advocated for the removal of children with visible types of disabilities from their communities to institutions, thereby reducing the need for general educational systems to concern themselves with their education. Before educational systems began to seriously consider the intersection of disability and education, a few individuals became interested in the topic (e.g., Itard in France and Montessori in Italy). As early as the 1800s, schools for children with sensory disabilities emerged with the intent of providing a context of support and expertise.

By the early 1900s, compulsory education for students with disabilities was well under way in the United States. At this time, there was a strong belief that it was best to segregate so-called backward and feeble-minded children. One significant challenge concerning function that educational systems faced was identifying children in the upper echelon of those with disabilities who might benefit from academic instruction. Intelligence testing quickly took root as an instrumental resource to assess students' functioning. At that time, the majority of special education services were centered on students with types of severe physical, visible disabilities, and physicians led these services.

In the late 1800s and early 1900s, the negative attitudes toward people with disabilities held by those in the growing eugenics movement, especially attitudes toward those who are limited cognitively, competed with early advances in educating children with disabilities. Although in the 1930s, the eugenics movement did interrupt these advances, new social attitudes toward children with disabilities soon began to take root. These attitudes posited that every citizen had a right to instruction to help him or her develop into an asset to society. In addition, parents began to organize and insist that government and schools acknowledge and address the needs of children with disabilities. In general, services were aimed at overcoming children's impairments and involved segregated schools or classrooms.

In the mid-20th century, a philosophical shift sparked social changes that improved educational opportunities for youth with disabilities. By the 1950s, in response to dissatisfaction with the isolation of children with disabilities, the National Association for Retarded Children, a powerful parent advocacy organization headquartered in Minneapolis, began to work toward policy changes. During this time, individuals with emotional disabilities—and later, in the 1960s, people with intellectual disabilities—began to move out of institutions and into the community, thereby increasing demand for community-based supports and opportunities.

Not only were parent advocate groups and organizations central to the struggle for equal educational opportunities for children with disabilities, but federal legislation has also served a critical role in securing the civil right of children with disabilities to a free and appropriate education. In large part, these acts have focused on understanding the types and functions of disability. More recently, an emerging understanding of the social construction of disability has moved forward positive practices and greater appreciation concerning the way social structures can promote well-being and success among youth with disabilities. Providing free and appropriate education continues to be a challenge, but substantial progress has been made since federal legislation provided a public policy foundation for special education in the 1960s.

Although the rights of children with disabilities were attracting greater attention by the mid-20th century, many children with disabilities continued to be excluded from the public school system. Parents and guardians pursued litigation to secure the educational rights of children with disabilities. These lawsuits established the importance of better identification of children with disabilities and offering children with disabilities a state-supported education. Soon after these lawsuits, the Education Amendments of 1974 (Public Law [P.L.] 93–380) were passed, which included an amendment renamed the Education of the Handicapped Act (EHA) Amendments of 1975 (P.L. 94–142). These amendments guaranteed that a "free appropriate education," inclusive of special education and related services, be available to children with disabilities in "the least restrictive environment" (LRE; also known as the *least restrictive placement*). It created a time line for ensuring full educational opportunity for all children with disabilities and procedural safeguards for their identification, evaluation, and placement. It mandated that, when possible, educators place children with disabilities in regular classrooms and that testing and evaluation materials not be discriminatory. The act denied schools the ability to exclude children with disabilities. The EHA was later amended to include incentives for early intervention, special education programs in preschools, and transition services.

In 1990, amendments to the EHA were renamed and led to the creation of the Individuals with Disabilities Education Act (IDEA) (P.L. 101–476). These amendments mandated transition programs that had to be considered in a student's Individualized Education Program (IEP), which is a yearly plan of a child's educational goals and supports necessary to achieve those goals. IDEA also expanded many discretionary programs including services and research/dissemination centers for children with specific forms of disability. Under the amendments of 1997, IDEA emphasized not only physical access to education but also, to a greater degree, involvement in the general curriculum involvement and outcomes for children with disabilities.

IDEA was most recently reauthorized in 2004 (P.L. 108–446). The new regulations align IDEA with the No Child Left Behind Act of 2002 (P.L. 107–110) and include an increased focus on accountability to ensure that children with disabilities are held to high standards. These amendments also require policies and procedures intended to prevent inappropriate overidentification or misdiagnosis of minorities as disabled, identify children with disabilities in foster care, and involve parents in decision making.

Disability Prevention and Diagnosis

In order to provide and evaluate appropriate educational opportunities for youth with disabilities, this entry examines both how disability is prevented and how youth with disabilities are identified in education settings. In educational contexts, prevention of the development of a disability involves the identification of and treatment of students who do not have disability but display risk factors (e.g., limited oral language ability, difficulty counting) that increase the likelihood of a disability later in life. For example, children with developmental speech/language impairments are at higher risk for reading disability than peers with no history of speech/language impairment. Therefore, the early identification and treatment of reading deficits may aid in preventing the development of a disability among such students.

The diagnosis of a disability remains rooted in a medical model emphasizing type and, to a lesser extent, functioning. The identification of impairment in an individual is often coded using either the *International Classification of Diseases* (Ninth Revision, Clinical Modification) (ICD-9-CM) or the *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision) (*DSM-IV-TR*). Individuals may be identified as having more than one impairment, including the primary diagnosis and any secondary conditions present. There are at least four important issues to consider in the diagnostic process: diagnostic methods, early identification, and two

diagnostic dilemmas—misdiagnosis and communicating effectively with parents.

Many disabilities are identified early in an infant's life, whereas others become evident when the child enters educational settings. Disabilities that may be diagnosed once the child is in educational settings include learning disabilities (LDs). *Learning disability* is a general term that describes a variety of specific kinds of learning problems. A learning disability may cause children to have trouble learning and using certain skills, including reading, writing, listening, speaking, reasoning, and mathematics. Learning disabilities are the most common disability found in children and adults: Almost 3 million school-aged children have some form of a learning disability and receive related special education services in school. More than half of all children who receive special education services have a learning disability. Approaches to the diagnosis of a disability vary depending on the nature of the disability; given the prevalence of learning disabilities among school-aged children, this entry describes the diagnostic process as an exemplar.

The most common approach to diagnosing an LD is a thorough, systematic evaluation of a child's strengths and weaknesses as a learner. These evaluative assessments may be written or oral, include an interview about the history and details of problems experienced, and are designed to identify IQ achievement discrepancies of students. However, the use of IQ achievement discrepancy procedures for the identification of children with learning disabilities has been persistently criticized because the diagnosis is based solely on the child's performance on IQ-related tasks and does not sufficiently consider other relevant factors. For example, such procedures do not take into account that environmental deficits, such as poor nutrition, may produce effects in a child's performance that mimic, rather than identify, a disability in a child.

Given the potential inaccuracies in identifying students with learning disabilities under this IQ-related method, alternative methods for identification and diagnosis have been offered, including response-to-instruction (RTI) models. RTI models are based on the premise that a student is identified as learning disabled when his or her response to an effective educational intervention is dramatically inferior to that of peers. Such models recognize that learning difficulty may lie within the child, within the instruction, or both. The models promote an earlier identification of LD, rather than waiting for students to show signs of failure, because the primary focus is on providing effective instruction and improving student outcomes. Diagnostic models that incorporate RTI characterize a shift in special education toward the goals of better achievement and behavioral outcomes for students identified with LDs, as well as those students at risk for LDs by heavily emphasizing both prevention and intervention.

During these diagnostic steps, early identification of students with disabilities to help them better understand and cope with their existing disability diagnosis is critical. Early detection is possible, and intervening earlier rather than later is most therapeutic and cost effective when addressing the needs and concerns of people with disabilities. Although there is a range of early intervention services that may be provided, they often involve physical, occupational, and/or speech therapy. Early intervention among those with LDs is important because the effects of learning disabilities tend to accumulate over time, and early detection can dramatically improve a child's life course and outcomes. As children fall behind in school, they may become more frustrated and increasingly feel like failures. Early detection is possible, and intervening earlier rather than later is most likely to be beneficial and cost effective when addressing the needs and concerns of people with disabilities.

Diagnostic Dilemmas

Currently, teachers in the United States determine whether a discrepancy exists between their expectations for a given student and the student's academic or social behavior in order to refer students to school psychologists for assessment of a disability. However, educators have been criticized for strategies that identify students of color, particularly those from low-income families, as disabled and place them in special education in the public school system. Nationwide, students of color are overrepresented in special education programs, indicating widespread misdiagnosis. Research suggests that some students of color are misdiagnosed with learning disabilities on the basis of biased assessments and assigned to remedial education programs that do not accurately address their learning needs. Overrepresentation in special education is most pronounced for Black children, who are nearly three times more likely to be labeled mentally retarded and nearly twice as likely to be labeled emotionally disturbed as White students in the United States.

There have also been criticisms regarding the identification and treatment of disabilities among students who are English-language learners. Students designated as limited in English proficiency are those who have received classroom instruction in English for less than 3 years and whom school personnel deem incapable of participating in statewide assessments in English. However, students born outside of the United States who have limited English proficiency are often inappropriately placed in special education programs based on tests given in English while in the United States. As a result, students with limited English proficiency are also disproportionately represented among students with disabilities.

Given the propensity of misdiagnoses, some experts believe identifying and diagnosing students with learning disabilities should be more holistic. Conscientious diagnostic personnel need to have an in-depth understanding of each learner and an awareness of the multiple competing factors in addition to a disability-related impairment that may give rise to lower test performance. They understand the right of every child to have an appropriate education in the least restrictive environment. The absence of these critical elements may jeopardize the effectiveness of both the prevention and identification of disabilities and of interventions for students with disabilities and their families.

Communicating a diagnosis of disability to parents can be challenging not only because of possible misdiagnosis, but also because of the process of accepting and understanding the disability and the ensuing need for modifications in rearing, educating, and advocating for a child that may be necessary. Parents' responses to having a child diagnosed with a disability may be diverse, both positive and negative. Timing; privacy in communicating; obtaining clear information about disability type, function, and social construction; continued and consistent contact with disability professionals; supportive counseling, and the understanding and support of family, friends, and school staff are important to help parents cope with the discovery of their child's disability. Once a disability has been identified, it is important to involve parents in managing the disability with their children. They are usually able to provide more ongoing support than others, and they often appreciate learning practical skills to help their children. Many parents report that, despite the considerable and sustained stress involved in parenting a child with a disability, their experiences have been personally and positively transformative.

Educating Youth With Disabilities

Upon a student's diagnosis with a disability, the school system needs to provide an appropriate education given the specific type of disability and learning needs of the student. Early intervention typically serves children from birth to 3 years old who have been identified as having a disability. Often, parents work closely with schools or other agencies to form an Individualized Family Service Plan (IFSP). From age 3 up until ages 18 to 21, the school system and/or other agencies provide educational and related support services as specified in the IEP. Given the diversity across disabilities, the ways in which youth with disabilities are educated and supported must vary accordingly. Interventions are generally specific to the disability and abilities of the student, such as extensive training for students who have limited reading skills. Intervention for a disability may be provided in a number of ways by teachers, peers, and/or parents.

Federal IDEA legislation requires that students with disabilities be placed in the least restrictive environment (LRE); that is, to the extent possible, students with disabilities are educated with students without disabilities. As such, many youth with disabilities are educated primarily by general education teachers. In general, teachers are expected to identify effective ways to meet the needs of a diverse group of students and ensure their success in the classroom. Regular education teachers often vary in their willingness, resources, leadership support, and preparation to make adaptations to their curriculum or teaching techniques to accommodate students with disabilities.

As educators place youth with disabilities in LREs, attention to both their physical and social integration is critical. Physical integration is the placement of students with disabilities in traditional learning classrooms. Social integration relates to facilitating opportunities for students with disabilities to build relationships with nondisabled peers and general education teachers. Physical integration into traditional classrooms is a precursor to social integration. Students with disabilities need to be learning in traditional classrooms where social interactions with nondisabled students and general education teachers can occur routinely before they can have the social opportunity to build connections with these peers and

teachers. Cooperative learning interactions between students with and without disabilities may promote an increase in supportive behaviors in students without disabilities to their disabled peers as well as greater frequencies of friendship and social activities outside of the classroom.

Determining appropriate classroom accommodations that a student may need given a specific disability is also a critical aspect to educating youth with disabilities. Outside of necessary accommodations to the physical environment, such as space for a wheelchair and room to maneuver it so that a student can participate fully in class activities, school and educational psychologists often direct their attention to the area of classroom instruction and testing accommodations.

The recognition that students with disabilities may need individualized instruction has also been applied to assessment, leading to individualized types of assessment and analysis of underlying processes thought to relate to the specific disability. Typically, learning assessment refers to state-mandated testing to determine student performance. Uniform performance evaluations present challenges to students with disabilities. Recently, constructive trends in assessment have shifted toward a greater use of assessments that are specific to a given subject matter, have curricular validity, account for contextual influences, and are developed from models of cognition. However, because school systems are often outcome based, minimum competency requirements apply to students with disabilities. Often, a marked discrepancy may exist between the curriculum taught and the content of standardized tests. Consequently, learning assessment and education of students with disabilities have many challenging issues that remain unresolved. Schools seek to understand and educate individuals with disabilities effectively and often distinctively in a context of limited resources, systemwide norms, and legal mandates.

School systems are also focusing on how to best prepare youth with disabilities for successful adult lives, including higher education, independent living, and competitive employment. This increased focus on transition has included attention to how to best involve parents in the transition process. Although IDEA has mandated since 1997 that transition planning begin at age 14, implementation has not been complete. Transitions plans, included in students' IEPs, usually focus on function and address the students' long-term goals, including employment preparation, technical training, or educational course plan. As such, educators need to be knowledgeable about each individual student's abilities and identify appropriate opportunities to best facilitate the goals outlined in the transition plan.

Educational Psychology and Students With Disabilities

Educational psychologists may determine how to administer assessments of students with disabilities and evaluate their results. They are able to educate teachers about appropriate types of instructional techniques and curricula for students with differing disabilities and abilities. Furthermore, drawing on existing studies and conducting research, they can adapt information and techniques used by special education teachers to be increasingly practical for a diverse classroom of learners. Educational psychologists are also often involved in evaluating the effectiveness of a specific intervention to determine whether the outcomes are appropriate and beneficial.

Educational psychologists can also facilitate successful transitions for students with disabilities by addressing their needs through increasing access, skill building and enhancement, and preparation for the transition ahead prior to their graduation from high school. They have been instrumental in developing transition programs that are effective and efficient for students with disabilities after high school, such as competence enhancement, job training, school-to-work programs, or college-preparatory programs.

In conclusion, the education of students with disabilities is one of the major challenges facing contemporary society. The historical record is marked by positive initiatives, good intentions gone awry, and malicious actions and policies. Over the past generation, society has come to recognize the potential of people with disabilities and has safeguarded these individuals to a much more significant degree than previously in law, policy, and practice. Schools are making a stronger effort than ever before—albeit partial, conflicted, and imperfect—to assess, educate, and transition children and youth with disabilities to positive futures. Using type, function, and social construction perspectives of disability, educational psychologists can enable schools to meet this challenge and enable students with disabilities to realize their full range of abilities and make valuable contributions to society.

DISCIPLINE

One of the results of the heightened concern about school safety is increased attention to school discipline as a factor in ensuring safe and orderly schools. Disruptive behavior in schools not only poses safety problems when incidents involve weapon possession, violence, or substance use, but also interferes with instructional efforts by teachers and with learning conditions for students. The most common understanding of the term *school discipline* involves punishment of student misbehavior by removal from the classroom or the school (i.e., office referrals, suspensions, and expulsions). School removal rates have been used as an indicator of safe and orderly school campuses. In the 1999 National Center for Education Statistics report, a high association was found between principal perceptions of discipline problems and school crime statistics. Within and between districts, higher numbers of disciplinary incidents are associated with higher rates of misbehavior. As well, there is an assumption that fighting and aggressive behavior can escalate into more violent events, and even nonviolent forms of student misbehavior can lead to unsafe school environments. High numbers of suspensions also have been associated with negative academic indicators such as grade retention, dropping out of school, alienation from school, juvenile delinquency, and drug use.

More recently, attention has been drawn to so-called low-level violence, or incidents of behavior, such as bullying, peer sexual harassment, and victimization. Chronic bullying has been characterized as a contributor to disturbed mental status and to the potential for retaliatory, aggressive, and perhaps violent behavior. As a result of greater awareness of the negative impact of incidents of low-level violence, such behaviors have been added to lists of suspendable offenses, along with more physical forms of threat and aggression. Zero-tolerance policies have taken disciplinary policies to an extreme, broadening the scope of exclusion to behavior that, although related, may not be associated with greater likelihood of violence and disorder (e.g., plastic knifes, ibuprofen tablets—interpreted as a "substance" being abused). These changes in school discipline policy are indicative of concern about behaviors that threaten psychological and developmental safety as well as physical safety.

Despite the recent association of school discipline with safe and orderly schools, historically, school discipline has included a broader range of practices that includes prevention of misbehavior, remediation of behavioral problems, and exclusion as a punishment for severe forms of misbehavior. The Latin root of the word *discipline* is actually from the verb "to learn." Thus, the broader conception of school discipline as an opportunity to teach positive behavior is in keeping with the roots of the terminology. This entry reviews the most recent trends in school discipline: It describes the process of zero tolerance as reflected in the indices of office referrals, suspensions, and expulsions; describes which students are being disciplined; and reviews best practices for implementation of

discipline practices that focus on the broader conception of discipline as an opportunity to learn.

School Removal: Rates and Groups

The Gun Free Schools Act of 1994 required states to have legislation to mandate the expulsion of youths who bring guns to school. As safe and orderly schools became of interest to this nation's educators, attention turned to gathering information about the rates of utilization of disciplinary measures. Research noted a dramatic increase in the use of exclusions in early and late 1990s. Nationally, whereas less than 4% of students across the nation were suspended or expelled in the 1970s, the 1990s saw those rates increase to 8% to 10%.

As these rates climbed, interest turned to the characteristics of this increasing population of excluded students. Students who find themselves involved in disciplinary incidents at school come to that place from a variety of circumstances. Students who are unlikely to pose a serious threat of danger to the school environment commit the majority of the offenses. They include a diverse group of students who take different pathways to the expulsion event and have strikingly different etiologies for their behavior. Not all students have a chronic history of discipline problems. Some come to the expulsion event through attendance problems, school disconnection, involvement in drugs, or a chronic history of emotional difficulties. Notably, however, students recommended for expulsion generally perform well below average in terms of grades and achievement scores. Thus, the one common red flag is poor school performance.

Two groups of students are particularly vulnerable to discipline under zero-tolerance policies: underrepresented minorities and students with disabilities. Data about suspensions and expulsions are consistent in the characterization of the overrepresentation of minority students. In particular, rates for African American students have been commonly reported as triple their representation in the student population.

Investigations reveal that African American and Latino students were more likely to be referred for discipline and more likely to be disciplined. Disciplinary actions were taken for these groups for minor misconduct, with the punishments seemingly out of proportion to the offenses. For example, discretionary offenses such as "defiance of authority" and "disrespect of authority" are more likely to be treated as exclusionary offenses with these populations.

Rates for students with disabilities have indicated double and sometimes triple their expected representation in the groups of students involved in disciplinary incidents. Special education students who find themselves in trouble at school are likely to have documented emotional, familial, or behavioral risk indicators that parallel their special education histories. Particularly salient risks for students include a history of attention deficit hyperactivity disorder (ADHD) or conduct problems, chronic or crisis-related family problems, and a history of inconsistent special education placements and interventions.

School Discipline as an Interaction Between Student and School Characteristics

Although general trends in the incidence and use of school disciplinary processes and general characteristics of students who are involved with these processes can be identified, there is great variation between schools in terms of how many students are disciplined and who gets disciplined for what behaviors. Student developmental and behavioral trajectories are inextricably tied to schooling practices. Appropriate practices may serve to reduce behavioral problems on a school campus, whereas lack of consistent and appropriate programming, education, and treatment may exacerbate developmental problems experienced by a student.

In addition to student and school environment interactions, student involvement in disciplinary events is not simply a one-time event; often, the interactions described above occur over time. There are risks and resilience (protective) factors within students and within their school environments that *precede* problem behavior leading to disciplinary actions. In the context of (*during*) delivering the consequences (office referral, suspension, expulsion), there are practices that improve or exacerbate the situation. Finally, intervention *after* the incident may cause additional risk or afford protection and positive development. Using the characterization of school discipline as a process (before, during, after) rather than an event and the framework of risk and resilience at the different stages of the process, school discipline and school removal will be described further in the following

stages: prevention, application of the consequence, and intervention.

Prevention:
Before an Incident Occurs

In recognition that student involvement in school discipline is affected by the context and environment of the schooling experience, an exploration of the philosophical orientation toward student discipline and student behavior is instructive. Despite the origins of the term *discipline* in a learning framework, student misbehavior has been viewed as a reason for excluding a student from school.

There is debate about whether or not schools are obligated to educate students who egregiously and continually violate school rules. For example, social maladjustment does not qualify for the protections and guarantees of free and appropriate education under special education law, despite the fact that these youths may present the greatest long-term social and economic costs to society. The assumption remains that somehow these students should lose their right to a public education if they cannot abide by the behavioral parameters set by schools. This social policy conflict may be result of the competing worldviews representing a "constrained" view (humans are imperfect; they misbehave, are responsible for that misbehavior, and should pay the consequences) and an "unconstrained" view (humans are perfectible; they misbehave due to special causes, ignorance, or social inequities; special circumstances require individualized application of consequences). In the constrained view, the obligation to educate a student ends after the behavioral transgression; in the unconstrained view, it does not. In the constrained view, expulsion is an event that ends the educational right; in the unconstrained view, the educational process continues, albeit with changes to accommodate the needs and behaviors of the student. The constrained worldview aligns with zero-tolerance policies, where little flexibility exists in applying the consequence or in considering the history and characteristics of the student who commits the offense. The unconstrained worldview involves a broader view of the influences on child behavior. This worldview supports the creation of educational and personal-social interventions to develop positive behavior rather than depend on punitive interventions. Students in schools where discipline practices are guided exclusively by the

constrained worldview are at greater risk of being excluded from school, whereas the unconstrained worldview is more likely to lead to "protective" discipline practices.

Preventing Misbehavior
at the School Level

The presence or absence of effective prevention programs that serve students with a range of risks and abilities is likely to affect the rates of school disciplinary events. Proactive school discipline programs have demonstrated effectiveness in reducing student behavior problems. The existence of a schoolwide discipline plan is a key strategy used in schools for preventing behavior problems that lead to student exclusion from school. Such a plan includes a clear statement of rules and expectations, consistently communicated and applied consequences for rule-breaking behavior, concrete efforts to teach students appropriate behavior, and positive consequences available for positive behavior. With this system in place and consistent implementation by all staff, students have a better chance of behaving in ways that will maximize their inclusion into the activities of the school.

The following essential characteristics of schools with low school disciplinary referrals have been identified: (a) Administrators and teachers demonstrate ownership of discipline-related problems that students present; (b) opportunities exist to develop strong bonds between teachers and students; (c) ongoing staff development is conducted about best practices in handling student misconduct; (d) a schoolwide code of conduct and expectations is promoted; (e) a process, location, and plan for students who need to "cool off" is available so that more severe outbursts can be prevented; (f) student sanctions are considered on a case-by-case basis with input from students and parents; (g) community participants are welcomed into the school, including parents, mental health and juvenile justice professionals, business leaders, and so on; (h) explicit efforts are made to show students that they are valued and respected members of the school community and that they are expected to uphold high behavioral and academic standards; (i) a wide variety of prevention and intervention support programs are available for students; and (j) the school physical environment is a friendly and welcoming space. These school characteristics add to the likelihood that students will stay within the behavioral standards of

the school and not be exposed to school removal actions.

Preventing Misbehavior at the Classroom Level

The classroom is one of the main contexts where a student's behavior comes into conflict with the rules and norms of the school. The teacher's ability to handle misbehavior and encourage positive behavior affects student behavior. A student who struggles with behavior issues in the classroom is at greater risk if a teacher has few strategies for addressing developmental lags and uses increased negative attention in an effort to control behavior. Teachers vary in their tolerance of and their ability to handle student misbehavior in their classroom. It is not uncommon to have a high number of referrals coming from a small proportion of teachers on a school campus. Classrooms that are characterized by low rates of academic engagement, praise, and reinforcement and that have high rates of reprimand are associated with high rates of misbehavior and show a cycle of negative student-teacher interactions.

In contrast, teacher management strategies, effective instructional techniques (e.g., class-wide peer tutoring), early intervention for students with learning problems, and positive teacher–student relationships are critical components for keeping students in the classroom or avoiding the necessity of excluding them for disciplinary reasons. Effective instruction and positive student–teacher relationships should be accompanied by opportunities for students to be involved in activities to promote the development of desired social and emotional skills.

The protective or preventive actions that are available to educators to help reduce misbehavior at school require strategies that are specifically aimed at teaching social skills and implementing behavioral strategies. Attention to building social skills and positive behavior may seem at odds with the current climate of academic accountability that is evident in this nation's schools. Time spent on direct student interventions or staff training on social and behavioral intervention may not get as much support or attention as similar programming for academics. Furthermore, some reports indicate that academic sanctions have made their way into school disciplinary logs (e.g., student detention for not finishing schoolwork or coming prepared to class). This situation reiterates the importance of considering schooling policies and trends as contributors to levels of school discipline utilization.

Protective Factors in the Discipline Process

Office Referrals

If a school has a graduated discipline process in place, the student trajectory through this process might look something like this. The student experiences several attempts by the teacher to keep him or her in the classroom. If these attempts do not work, an office referral may result. Risks to students at the office referral stage exist when there is no systematic agreement about behavioral expectations within classrooms and throughout the school. There may be wide variations from teacher to teacher about what constitutes behavioral transgressions. Whereas some teachers may refer many students for small transgressions, some may refer few and use the referral for significant rule-breaking behavior. One often-ignored risk occurs when any one student is referred many times and spends a significant amount of time away from the classroom, thereby missing important academic engagement time. Another risk is when the intervention at the office or principal level is ineffective. The student thus not only misses academic time, but also learns nothing from the experience.

Protective factors may be built into the office referral system. Schoolwide agreement on what constitutes an office referral, systematic collection of data to determine the incidence of student behaviors, and examination of teacher referral patterns are practices that allow for periodic examination of the effectiveness of existing behavioral interventions. Examination of who gets referred for what is likely to reveal that a small group of students is involved in the majority of referrals. The intervention for these students should then be intensified. Early, effective intervention for misbehavior serves as a preventive mechanism for continued trajectories toward serious behavioral problems.

Suspension

Suspension from school is a more serious consequence that is regulated by state and local statute. Most states, as guided by the Gun Free Schools Act, mandate suspension and expulsion for possession of a weapon (firearms or bombs) at school. States recently

have added offenses to this list that include threats, sexual harassment, and bullying. Although suspension is required for the most serious offenses, discretion of the school administrator is available for lesser offenses such as school disruption, defiance of authority, attendance problems, tardiness, inappropriate dress, and so on. It is in the areas of discretion where possibilities for risk and protection exist. Zero-tolerance approaches to suspension, even for minor offenses, lead to higher levels of suspension, which are associated with lowered school effectiveness. One reason for this association is that suspension as an educational strategy has not been proven effective. Whereas school exclusion of students who pose a danger to the school makes sense for achievement of safe and orderly schools, suspension for lower-level offenses, as with office referrals, leads to reduced academic engagement time and may not lead to the desired change in future behavior. Automatic exclusions, in the absence of exploration of the root causes of misbehavior or without intervention designed to specifically address the problem behavior, contribute to limited effectiveness of the suspension.

In order to avoid overuse of suspension as an ineffective consequence for misbehavior, it should be used thoughtfully and judiciously. Data on who gets suspended for what offenses should be carefully monitored. As with office referrals, repeat offenders account for a good proportion of the suspensions, and appropriate interventions can be targeted to this group. Schools now use in-school suspension in order to monitor out-of-class time and lessen the impact of loss of academic engagement time.

Expulsion

Suspension is the first step toward expulsion. School administrators must recommend expulsion for some offenses. The balance that school administrators must face in final expulsion from school is maintaining the safety of their school campus and denying the educational opportunity of the student being excluded. The risks for the student are those associated with violations of due process and bias that may enter the process, resulting in an unfair exclusion from school. The factors associated with how students arrive at the expulsion event may be framed as risk factors; that is, students who get expelled demonstrate risk in areas of ethnicity, disability, school maladjustment, lack of parent advocacy, and alienation from activities and people at school.

However, there are protections embedded within the school expulsion process. The final decision about school exclusion is a school board decision. The board may have the discretion to suspend the expulsion order and return the student to the district, perhaps to another school within the district. Furthermore, many states now require that alternative education be provided to students upon expulsion. Another positive influence on a district action to stop short of expulsion is the presence of an advocate in the student's school, community, or family. These individuals might vouch for the overall character of the student, ensure that due process is being followed, or advocate for the continuity in current educational and therapeutic interventions. A student who has multiple positive factors in his or her school record (e.g., extramural activities, leadership roles, good grades) is less likely to receive the full expulsion consequence. Finally, special education services and support serve as a deterrent to school expulsion (i.e., beyond the initial recommendation), especially given the protections provided to special education students under federal law.

Continued examination of school expulsion data, as with office referral and suspension indices, is recommended in order to provide a check on who is being expelled and what outcomes befall students who are expelled. There is a dearth of information about outcomes for expelled students in the research literature to date.

Use of School Discipline Indices

A cautionary note about disciplinary indices is offered here. Despite attempts to associate group- and individual-level statistics with negative, risky outcomes, these indices are not necessarily intended to serve as reliable and valid measures of misbehavior. Rather, they have been developed as legal and record-keeping measures. Office referrals help communicate between teacher and principal about student misbehavior. Suspension and expulsion data result from legal due process procedures for excluding students from school. Because these indices were not necessarily intended to be used for group and individual description and prediction, these systems are fraught with error in design and implementation. This lack of reliability of office referral, suspension, and expulsion counts compounds the basic challenge of finding evidence that these processes are effective. The increased use of suspension/expulsion is especially

contradictory within an educational/political climate that demands utilization of evidence-based practice.

Intervention After Disciplinary Actions

A student may receive suspension from school and never get in trouble at school again. However, students often continue to reoffend and need more intensive intervention for their behavior and its underlying roots. As an alternative to school removal for recurring misbehavior, the most common interventions include targeted interventions for misbehavior and aggression and placement in alternative settings.

Targeted Interventions

Targeted interventions may include intervention for the student's problem behavior (anger management, conflict resolution, social skill instruction) as well as intervention in the nonschool settings in the student's life (home, community). FAST Track is an example of a comprehensive program that includes intervention in the student's home (parent training) as well as in school (academic tutoring). The Multisystemic Therapy (MST) program is an evidence-based program that includes intensive, therapeutic intervention within the student's home environment. Another targeted intervention receiving attention is restorative justice. A restorative justice program involves the offender and victim in a process of identification of the offense and attempting to repair the damage. This type of program facilitates the building of relationships and sense of community as opposed to punishment-based exclusion.

Alternative Settings

Alternative education programs may provide services to students who have been expelled, but not all students who are expelled are afforded the right to attend an alternative education program. There are no federal laws mandating that all states provide alternative education placement for students who are expelled. Currently, the decision as to whether these alternative programs are discretionary or mandatory in nature varies state by state.

Perhaps because of the wide variety of students served, as well as the differing legislation across states regarding implementation of programs, very little is known about how well alternative education placements serve students, particularly those who have been expelled. Some programs have made claims that their alternative education programs have had some success in (a) providing GED completion, remedial assistance, and vocational training; (b) developing communication, coping, and self-control skills; and (c) keeping students in school. Strategies that are likely to lead to successful alternative education programs include the following: (a) low student–teacher ratio, (b) highly structured classrooms with behavioral classroom management, (c) positive rather than punitive emphasis in behavior management, (d) availability of adult mentors, (e) individualized behavioral interventions based on functional behavioral assessment, (f) social skill instruction, (g) high-quality academic instruction, and (h) parent involvement.

Involvement in either targeted interventions or in alternative education provides students who have been excluded from school the protective opportunity to gain skills that will be necessary to re-engage in the school environment in a productive way. Students who do not receive programming to build skills and change behavior are at high risk for failing again upon their return to the school environment.

Best Practices

To summarize the basic principles of best practices in school discipline, the American Bar Association passed a resolution in which it outlined three principles that apply to the protective processes described in this entry. The Association opposed schools' zero-tolerance disciplinary policies that fail to take into account the circumstances or nature of an offense or an accused student's history. It supported three principles concerning schools discipline: (1) Schools should have strong policies against gun possession and be safe places for students to learn and develop; (2) in cases involving alleged student misbehavior, school officials should exercise sound discretion that is consistent with principles of due process and consider the individual student and the particular circumstances of misconduct; and (3) alternatives to expulsion or referral for prosecution should be developed that will improve student behavior and school climate without making schools dangerous. Effective practices associated with these principles will keep students in schools; ineffective practices will create a great risk for student removal from school.

DISCOVERY LEARNING

Issues concerning human learning are among the critical topics in educational psychology, child development, and cognitive science. One central focus has been on the issue of how students learn and teachers teach best, and discovery learning versus direct instruction has been a contentious debate in modern educational theory and practice. Stemming from the theoretical perspective of constructivism, discovery learning is believed to be a tool for facilitating the creation and organization of knowledge, as well as the transfer of that knowledge across different contexts. This approach contrasts with views that emphasize direct instruction from teacher to student. This entry addresses the following central issues: how discovery learning is defined, the empirical evidence in favor of discovery learning or direct instruction, and the facilitation of discovery and transfer.

Definition

Discovery learning is a general approach that involves mindful participation and active inquiry in the acquisition of concepts and strategies. In classroom contexts, it refers to a form of curriculum in which students are encouraged to actively explore and figure out the concepts, solutions, or strategies at hand. A widely accepted idea is that discovery learning is the most appropriate and effective approach to facilitating deep and lasting understanding. This approach is often contrasted with direct instruction or expository learning, which typically refers to traditional, content-oriented methods whereby the instructor lectures to students. Learning associated with direct instruction is often believed to be less engaged and less active, and thus less effective.

The spirit of discovery learning can be traced back to philosophical traditions. The French philosopher Jean-Jacques Rousseau believed that children do not learn well via instruction and therefore should be given maximum freedom to explore their surroundings. He claimed that children learn primarily from spontaneous exploration of the environment and from interactions with people and objects. John Dewey posited that the essence of education is learning by doing and exploring. According to Dewey, discovery learning provides the "intimate and necessary relation between the processes of actual experience and education."

Discovery learning is at the core of the constructionist view of education. According to Jean Piaget, children learn by interacting with the environment, both physically and mentally. He emphasized the importance of "cultivating the experimental mind." Educators must teach children how to use discovery as a tool for constructing and acting on their worlds. Another constructionist, Jerome Bruner, was an early advocate of discovery learning environments. He believed that allowing students to learn by constructing knowledge structures would lead to improved intellectual ingenuity and persistence, as well as increased motivation to learn. He claimed that

emphasis on discovery in learning has precisely the effect on the learner of leading him to be a constructionist, to organize what he is encountering in a manner

not only designed to discover regularity and related-ness, but also to avoid the kind of information drift that fails to keep account of the uses to which information might have to be put (Bruner, 1962, p. 87).

Thus, discovery learning is effective at helping the student uncover the underlying principles of a domain and in generalizing that knowledge to other tasks and contexts. Despite the widespread appeal of discovery learning and strong endorsements by a wide range of theorists and educational researchers, major issues and controversies remain regarding the role of discovery in learning and the evidence supporting this approach.

Empirical Evidence

Over the past half century, psychological researchers and educators have engaged in substantial debate about which approach, discovery versus expository learning, is more appropriate and effective. Although many have favored discovery learning over expository learning, others argued against discovery learning. More recent empirical research has generated mixed findings supporting each view. In particular, there are two related issues concerning the role of discovery or direct instruction in learning outcomes: (1) Can students *discover* strategies or rules? If so, (2) can they *transfer* what has been discovered to other contexts and situations?

The first issue is whether students are capable of making discoveries on their own, rather than being taught. There are ample examples of students' discovery of problem-solving rules or strategies. For example, even 5- and 6-year-old children are capable of discovering new rules for solving problems on the balance scale task. This task involves making predictions about whether the scale will go down on one side or stay level when a set of weights is placed on each side of the scale. How the scale moves depends on two factors: the number of weights placed on each side and the distance of the weights from the fulcrum of the scale. Children at this age typically make predictions based on the amount of weight on each side, but not distance. However, after having an opportunity to make predictions and then observe how the scale moves, children discovered the relevance of distance to the task. Therefore, children discovered a more advanced problem-solving rule in the sense that the experimenter never explicitly told children to pay attention to the dimension of distance.

Still, the effectiveness with which students discover rules or strategies depends on the mental activities in which the students engage and the guidance that teachers provide during the learning process. Discovery learning ranges from *pure discovery* to *guided discovery*. For the former type of learning, the learner explores the problem area in an unconstrained environment without direction or feedback from the teacher. In contrast, the latter type of learning involves supervision and guidance during the discovery process. In a 2004 article in *American Psychologist*, Richard Mayer reviewed studies of discovery learning between the 1960s and 1980s and argued that evidence in support of guided discovery was more prominent than for pure discovery. The findings of discovery learning of problem-solving rules, conservation strategies, and computer programming concepts all indicated that pure discovery is much less effective, as the learner often fails to recognize key principles and strategies and thus is not able to assimilate new experiences with existing knowledge. In contrast, guided discovery has proven to be more effective than pure discovery in promoting learning and transfer. Learners benefit from scaffolded experience, whereby the instructor provides constrained problem spaces to explore, encourages cognitive activities, or redirects learners when they went astray.

Another related issue is whether learners transfer more effectively when rules or strategies are discovered or when they are taught directly. Several studies have demonstrated that students who discover new concepts or strategies are more likely to extend this knowledge to new tasks than those students who learn from direct instruction. For example, in a 1990 paper in *Cognition and Instruction*, Mark McDaniel and Mark Schlager explored college students' strategy learning in solving Luchin's Water Jar problems. In this task, the solver must use a given array of three jars (A, B, C) to measure out a particular amount of water into a larger jar. Solution of the problem typically requires the use of an equation based on a combination of the three jars (e.g., $1A - 1C - 2B$). It was found that requiring learners to discover a solution strategy for this problem led to better performance on a transfer problem, which required the generation of a new solution equation. Thus, requiring students to generate equations based on the given tools proved to be most critical, and discovery conferred benefits beyond instruction.

In contrast, other experimental research comparing learning and transfer outcomes between instruction

and discovery suggests otherwise. In a 2004 *Psychological Science* article, David Klahr and Milena Nigam compared elementary school children's learning and transfer of the Control of Variable strategy in experimentation. They assessed children's conceptual understanding that only unconfounded experiments generate clear experimental evidence. Specifically, children were asked to design appropriate experiments based on the manipulation of appropriate variables and control of potentially confounding variables. In this study, one group of children was taught the strategy through direct instruction—an experimenter explained the importance of controlling confounding variables and manipulating variables of interest. A second group of children was allowed to interact freely with the problem materials. Therefore, if the children learned the strategy, it was through a process of discovery. The results showed that more children in the instruction condition learned the strategy compared to the children in the discovery group. Furthermore, many more children in the instruction condition were able to transfer what they learned. Numerous other lab experiments and classroom studies have also demonstrated the importance of instructional support and intervention during learning of mathematical and scientific concepts.

These mixed results suggest that it might not be productive to simply classify learning as discovery based or instruction based. Whether children discover target rules or strategies and how they transfer what they learn to other tasks depend on children's ages, their initial knowledge, the nature of the tasks, and the cognitive activities engaged during the process of learning. These seemingly contradictory findings, in fact, point to the need to recognize various forms and types of discovery learning between the two extremes of the spectrum: direct instruction and pure discovery. Perhaps the key is how to provide guidance during discovery. Psychological studies have pointed to several promising approaches to promoting discovery and transfer.

Facilitating Discovery and Transfer

Task Selection

A teacher's guidance can play a critical role in supporting discovery when learning materials are carefully organized and presented so as to streamline the discovery process. For example, in a 1976 study published in *Cognitive Psychology*, Siegler provided some

5-year-old children with feedback from problems in which the weights were the same on both sides but were placed on different pegs from the fulcrum. Other children received feedback from more complex problems in which one side had more weight, and the other side had the weight farther from the fulcrum. The first group learned more effectively and discovered the role of distance, whereas the second group did not learn to incorporate the distance dimension into their predictions. This moderate-discrepancy hypothesis suggests that the most effective experiences for promoting discovery are those that are somewhat, but not greatly, beyond children's existing problem-solving abilities. The role of guidance in organizing tasks for facilitating discovery is also evident in a study with college students by Zhe Chen and Mo Lei. Students who received more diverse instances of Luchin's Water Jar problems (diverse equations such as $1A - 2B + 1C$ and $1A - 2C$ and different types of problems such as volume, length, and area problems) were more likely to formulate a general problem-solving principle and apply it to novel tasks than these who received very similar tasks.

Guiding Questions and Self-Explanations

Another approach for effectively guiding discovery is the use of probing questions to direct students' attention to important features of the problem. In the case of learning the Control of Variable strategy, Chen and David Klahr conducted a study, published in 1999 in *Child Development*, in which they compared and contrasted two learning conditions in which elementary school children learned the Control of Variable strategy. The children's task was to design a series of valid experiments. In each, a single contrast was made (e.g., setting up two ramps that differ only in steepness, but not in other variables, in order to test the effects of steepness on how far a ball would travel down on the ramp). Although no explicit rationales were provided in either condition, two learning conditions differed in whether the experimenter asked children to explain why they designed a particular test and how they would interpret the experimental outcomes. Children in the directed questioning, or probe, condition thus had the opportunity to generate explanations of their reasoning behind their choice of objects for their experiment and for the possible conclusions from their design. The results indicate that elementary school children benefit from the systematic questions designed to promote deeper understanding. In contrast, allowing

a child to interact freely with experimental materials/ devices without asking guiding questions is insufficient for promoting discovery and transfer. Children's superior performance in learning and transferring the Control of Variable strategy in the probe condition further supports a growing body of studies demonstrating that the opportunity to generate self-explanations enhances children's learning.

Self-Generations

A number of studies have demonstrated the effects of mental activities during learning on discovery. Requesting students to generate evidence for their own opinions or to provide instances of principles has proven effective for fostering deeper understanding. Earlier research suggests that beginning lessons by asking students to generate their own ideas about phenomena, instead of directly telling students correct answers, is effective in facilitating formula comprehension and solving transfer problems. Similarly, encouraging students to generate concrete examples of abstract principles has been found to enhance understanding of the concepts and facilitate subsequent transfer. Other recent studies have shown that when students are asked to recall similar information, they tend to use superficial information in solving problems. In contrast, when students are required to process information by generating analogies, they tend to use underlying structural information.

Future Research

Discovery learning has long been favored as an effective approach to acquiring concepts, rules, and strategies. Despite the lasting and widespread appeal of active, mindful, explorative, and inquiring-oriented learning, the concept of discovery learning has been more of a philosophical belief or educational ideology than a pedagogical method that is grounded in and guided by empirical findings. Empirical research has suggested that guided discovery appears to be a better approach to promoting learning than pure discovery, and it has pointed to several approaches to promoting discovery and transfer during learning. A fruitful avenue for future research, according to Mayer, would be to explore precise mechanisms involved in discovery learning, in particular the quantity and quality of guidance that results in optimal learning performance. This type of empirical evidence generated from lab and classroom experiments can then be extended to and used to guide educational practice. Commonsense beliefs about the importance of inquisitiveness can then be separated from empirically driven educational practices, and discovery learning would then be established as a truly evidence-based educational method.

DISCRIMINATION

In the social sciences, *discrimination* refers to the differential treatment of people as a function of their group membership. Because many people experience

discrimination over the course of their lives, and because people may discriminate without conscious awareness, discrimination is an extremely relevant topic within educational psychology. This entry defines *discrimination* and then explains its causes and consequences. Finally, several attempts to combat discrimination will be described.

Definition of Discrimination

Discrimination includes differences in verbal and nonverbal behavior, such as when a White interviewer makes speech errors or less eye contact when interacting with an African American as opposed to a White job applicant. Discrimination may also be blatant or subtle in form, and it may be intentional or unintentional. For instance, discrimination may include obvious acts of aggression, social exclusion, differences in the allocation of valued resources (e.g., raises and promotions), or subtle acts of condescension. Discrimination may, at times, seem to be characterized by seemingly kind acts, as well as negative acts. Traditional women and elderly people, for instance, may be excessively praised for accomplishments because such accomplishments are not expected of women and elderly people. Importantly, however, such praise tends to be condescending because it has an implicit qualifier, such as "Wow, she's great, *for a woman!*"

Members of many different groups may be targets of discrimination. These groups include, but are not limited to, women, racial minorities, elderly people, gay men, lesbian women, immigrants, people who live in poverty, people with physical disabilities, and overweight people.

Causes of Discrimination

Discrimination is thought to follow from prejudice and stereotyping. Although this is often the case, stereotyping, prejudice, and discrimination are distinct constructs.

Stereotypes, prejudice, and discrimination are typically conceptualized as the three components of intergroup attitudes. Prejudice refers to the *affective* component of an attitude. It describes the way a person feels about a particular group, which can be negative or positive. Stereotyping refers to the *cognitive* component of an attitude. In other words, stereotypes are beliefs about a particular group. Like prejudice, stereotypes can have negative and/or positive content.

If someone thinks that women are warm and communal, but not influential and leader-like, then that person holds a stereotype about women. Discrimination refers to the *behavioral* component of an attitude.

Discrimination is a complex phenomenon that sometimes stems from prejudice. Some theorists, for example, argue that prejudice often is expressed through ingroup favoritism. People tend to value that which is and those who are familiar, and people tend to protect their values through ingroup favoritism. Others have linked prejudice and discrimination to personality constructs, such as the authoritarian personality (characterized by preoccupation with power, authority, and adherence to cultural ideals). Importantly, discrimination is related to the natural and adaptive mechanisms humans use to negotiate and make sense of complex social contexts. People view themselves as group members to satisfy the need to belong and to achieve positive social identities. By associating with groups and differentiating one's own group from other groups, people can belong to valued groups and achieve a positive sense of self. Ironically, adaptive self processes are often associated with discrimination, or favoring one's own group at the expense of the other groups.

There is also ample evidence that stereotypes and discrimination are linked. For instance, educational and social psychologists have conducted research on self-fulfilling prophecies, particularly in educational settings. The concept of self-fulfilling prophecy was first put forth by sociologist Robert Merton, who suggested that one person's expectations about another person could cause changes in that other person's behavior. Picking up on this idea, Robert Rosenthal and Lenore Jacobson published their famous "Pygmalion in the classroom" study. These researchers led teachers to believe that certain students in their classroom were "late bloomers," thus creating the expectancy that these students had traits that would lead them to be stars in the classroom. The so-called late bloomers were, however, randomly selected. Nevertheless, compared to a control group of students, the late bloomers showed more striking gains in IQ over their elementary school years. Rosenthal and Jacobson's seminal research inspired much theory, research, and debate. After nearly four decades of theory and research on self-fulfilling prophecy effects, and related outcomes, most acknowledge that stereotype-based expectations influence behaviors in ways that reinforce and maintain stereotypes, and the status quo more generally.

Although expectancies can be formed consciously, the self-fulfilling prophecy effect can be considered unconscious in that people don't purposely set out to change the behavior of others through their expectations. However, stereotyping can also influence discrimination at an unconscious level. For instance, stereotypes can be automatic in that when a person sees someone else, he or she automatically processes certain key information about that person (the person's age, race, and gender) without conscious awareness. This categorization activates stereotypes associated with particular groups. For example, when someone categorizes another person as African American, stereotypes about African Americans become activated. Thus, the person who is doing the categorizing may behave in discriminatory ways based on the group to which the target was ascribed. For instance, the perceiver may stand further away from the person being categorized than if that person had been categorized as White.

Consequences of Discrimination

Discrimination often has damaging consequences. For instance, many scholars have theorized that discrimination leads to decreased confidence and self-esteem. Although this idea has been challenged, evidence remains that discrimination leads to harmful emotional effects. These include anxiety, self-doubt, decreased confidence, increased anger, and fear of confirming negative stereotypes.

In addition to psychological consequences, discrimination may result in tangible, everyday harms. One of the most frequently documented cases of discrimination involves "equal pay for equal work." Although women frequently do not realize that they are the victims of discrimination because they do not have access to the financial records of men in their companies and therefore do not know that they are earning comparatively less, they still earn an average of only 76 cents for each dollar earned by men.

Discrimination can also adversely affect academic performance. Members of stigmatized groups often underachieve in academic settings. This could be due to many factors, including the students' fears of confirming stereotypes about their groups. This phenomenon is known as *stereotype threat.* Thus, stereotyping leads to decreased academic performance, which in turn leads to discrimination, as grades and standardized test scores influence hiring and admission decisions. This results in a system whereby members of stigmatized groups experience discrimination due to their underperformance on academic tasks, which is at least partially the result of stereotypes about their group.

Combating Discrimination

To reduce discrimination, the U.S. government has implemented several policies, including affirmative action. Affirmative action began in 1965, when President Lyndon B. Johnson signed a mandate requiring federal contractors to not "discriminate against any employee or applicant for employment because of race, color, religion, sex, or national origin" and to "take affirmative action to ensure that applicants are employed, and that employees are treated during employment, without regard to their race, color, religion, sex or national origin."

Affirmative action has created controversy with regard to employment and admission to institutions of higher education. In the 1978 *Regents of the University of California v. Bakke* case, the Supreme Court ruled (five to four) that universities could consider racial heritage when making admissions decisions. In 2003, the Court upheld this decision in cases involving the University of Michigan by ruling that race can be one of many factors considered in admissions. The Supreme Court further ruled, however, that point systems such as those used by the University of Michigan's undergraduate admissions program had to be modified because they do not provide individualized consideration of the applicants.

Nongovernmental intervention programs have also been implemented across the United States. For instance, one study found that African Americans performed significantly better in school when asked to write about values that were important to them as a way to reaffirm their sense of personal adequacy. Such intervention programs suggest that the harmful effects of discrimination can be reduced through strategies targeting stigmatized group members.

DISTANCE LEARNING

Distance learning is a term in wide use today. Educators also refer to it as *distance education* and, in some settings, *distributed education.* For the purposes of this entry, *distance learning* is defined as the communication over distance between teacher and student mediated by print or some form of technology designed to bridge the separation between teacher and student in space or time. Advances in information and communication technology are changing the manner in which instructors have traditionally conducted distance learning, and these changes are providing many transformational possibilities for all levels of education. With the development of many online tools and the easing of prices for handheld computers and audio/video players, students are increasingly able to shift their distance learning experience not only beyond temporal necessities, but also into new physical environments. Research libraries with access to full-text documents are as available to students as are lectures and symposia either streamed live or delivered asynchronously. Educators could argue the case that advances in information and communication technologies may make distance learning even more interactive than face-to-face teaching and far less distant than once considered.

After an examination of the origins of distance learning and a review of its basic features, this entry examines some of the effects on pedagogy of course management systems and other telecommunications tools that are transforming the nature of schooling, lifelong learning, and communities of learners.

Origins and Evolution of Distance Learning

Distance learning has been available in one form or another for hundreds of years. One of the earliest examples of distance learning occurred in England in the 1840s. The Pitman Company offered training in shorthand through a series of lessons mailed to students across the country. In hindsight, this was very much a one-way, noninteractive approach to distance learning.

Until recently, public interest in distance learning was especially high only where there was a widely distributed student population. One of the more famous modern examples of distance learning took place in Australia. Beginning in 1951, the School of the Air officially opened to broadcast, by radio, lessons to the children of the Outback. Beginning with one-way transmissions, coordinators soon added a question period to follow the broadcasts. Interactivity, even in the beginning stages of technology-enhanced distance learning, was highly valued.

Today, many institutions of higher education, both public and private, are making use of distance learning to broaden the reach and scope of their particular curricula. Of course, it is very important that students who participate in distance learning are self-motivated and able to work independently, but teachers also have a particularly vital role to play in the process of distance learning and its overall evolution.

Basic Features of Distance Learning

Distance learning and distance education programs are experiencing a boom of sorts with the advent of the Internet and the ability to transmit increasingly large audio and video files over increasingly available and accessible bandwidth. A proper examination of distance learning must begin by determining how distance learning differs from face-to-face learning. In fact, many research studies focusing on the efficacy of distance learning compare it with face-to-face learning. For that reason, researchers view many of the tools and affordances of modern distance learning

as supplements to or extensions of traditional or face-to-face learning experiences.

One of the most basic features of traditional or face-to-face learning for the student is the ability to listen to and interact with the instructor. Distance learning, using a variety of tools and technological affordances, can replicate the primary experience of listening to an instructor using audio files downloaded and played on a computer or portable listening device. Advances to this technology also enable students to view the instructor and available visual aids on convenient handheld devices. The availability of such files leads to another feature of distance learning, the ability to shift the learning experience out of classroom into a different time and place. This distribution of the learning experience is known variously as "phase shifted learning," "asynchronous learning," and "any place any time learning."

Transactional Contact

Another important and essential element easily accomplished in face-to-face instruction is transactional contact, or the ability of the instructor to interact with the student. With the advent of several software tools, instructors can shift their transactional contact with students beyond the classroom. Instructors accomplish this in two different ways.

In one way, the instructors retain the ability to speak and even see the student over distance in real time. Instructors accomplish this interactivity relatively inexpensively with a simple web camera working in concert with instant messaging software. There is available to instructors a range of sophisticated video conference systems that transmit video and audio over the Internet. These systems make use of an Internet networking protocol widely referred to as "Video over IP." An earlier version of this protocol, which is still in use, makes use of ISDN or Internet Subscriber Digital Networks to allow for two-way video conferencing.

The other way of maintaining close transactional contact between the instructor and the student is asynchronously using software-driven quizzes and reviews of instructional material that provide automated feedback to the student. Instructors can provide this feedback in varying intervals, for example, after the submission of responses to a series of questions or upon the submission of a response to a single question. Variations of this technique are gaining greater

use within distance learning environments. One example is to provide the conditional release of assignments so that before students can progress to the next stage or segmented element of learning, they must demonstrate, in some manner, a degree of understanding the material. The ability to automate this mastery learning technique is a tool that is causing some instructors to revamp the pedagogical structure of their courses.

Distributed Learning Materials

One of the basic elements of distance learning that technology has enhanced recently is the ability for instructors to distribute reading materials for courses quickly and efficiently as electronic documents accessible across computing platforms. Many instructors use the ubiquitous portable document format also known as PDF, which requires a free software reader. The instructor creates these documents, gathers them from online sources, or scans them directly from a primary source.

It is not only documents that can be distributed in this manner, but also spreadsheet files, still photographic images, software programs, and even movies. Such a wealth of resources, commercially available and user created, allows for the possibility of increased opportunities for reinforcement or for the reteaching of concepts. Resources such as these are known as Learning Objects. Many distance learning projects may store them in what is known as a Learning Object Repository (LOR) and make them available to other institutions and professors so they do not need to reproduce work that another colleague has already done.

Modification of Pedagogy

Such a wide availability of tools and resources also allows the instructor to guide the student to the pedagogical experience and learning environment that is most suited to the learning style of the student. Such an explicit design of the learning experience, one that the instructor can tailor directly to the learning style of the student, is a great challenge to instructional design experts and still the goal of many creative instructors.

In addition to modifying instruction to learning styles, the latest technological affordances improve instructors' ability to present materials to accommodate physical impairments or disabilities. For example,

students may use text-reading software to read and review class materials, and students with visual impairments can use adaptive technologies to increase or improve the visual presentation of materials using the adaptive technologies of their choice.

Course Management Systems

With so many tools available to instructors, an essential element of distance learning has become the Course Management System, sometimes known as CMS, or a Learning Management System, or LMS. These management systems make available to instructors a variety of tools they may opt to use to make the distance learning experience uniquely tailored to the course content. The potential tools and affordances, of course, can be broken down along various continua, such as content rich versus content poor or synchronous versus asynchronous.

Discussion Lists

Discussion lists are primarily asynchronous, text-based opportunities for students to respond to questions and discussion topics and to interact with each other in the familiar environment of their e-mail program of choice. Innovations in this area are allowing students to leave video or audio messages for each other and their instructor.

Threaded Discussions

Commonly known as discussion boards, threaded discussions are web based, and the instructor can set the degree to which students may respond by limiting length of response or the number of responses. One benefit of the threaded discussion is that instructors can populate the discussions with small groups of students and change those groupings as needed.

Chat

Chat, sometimes known as the Internet Relay Chat (IRC), allows multiple participants in the course to enter a text-based environment to correspond with each other and the instructor. An unfortunate drawback of this tool is that students sometimes have difficulty following multiple conversations simultaneously. For this reason, many course management systems allow students to color code their text to make it more easily recognizable by others in the conversation. Some course management systems allow the use of images or avatars to represent the speaker in a conversation.

Internal Communication

Course Management Systems sometimes employ their own e-mail services that are accessible only when the students log on to the course. Also widely available are tools for instant messaging or paging another individual in the class when students log on to the system. Recent iterations of this tool allow the posting of video messages.

Presentation Tools

Instructors who employ visual slide presentations in their face-to-face teaching can post the presentation in its entirety to the online course. They can also use many available tools to capture their speech and include their narration with the presentation or post their narration as an enhanced podcast that students may review asynchronously. Using other widely available tools, instructors may also capture a sequence of keystrokes to illustrate a technique or the steps necessary to operate a software program. They may also use an electronic white board enabling the instructor to interact with graphical elements in the course using a digital marker.

Digital Content

Distance learning also enables students to participate in the creation of learning objects that the instructor can share with the class or other colleagues. One of these techniques is to create a repository of digital objects for analysis and critique by other students in the course. Depending upon the nature of the digital objects, such as images, movies, software, and Web pages, there are several systems by which students may access these objects. For example, students may create a glossary for use by fellow students. Students may also make use of a tool known as a wiki, which will allow classmates the opportunity to edit a living document as the knowledge base is refined, improved upon, or corrected.

Instructors also may make use of the repository of digital teaching tools created by their peers in the field. Instructors add these digital tools to the digital repository and tag them with key words, sometimes known as metatags, which allow the repository to store and retrieve the objects with ease. The rise of

this method of exchanging digital teaching tools has led to the development of standards for the industry. The Sharable Content Object Reference Model (SCORM) is the standard for tracking records in learning management systems. The benefit of having this sort of repository is that the users, both students and instructors, can go to the database, or repository, to view or download tools.

Issues Related to Distance Learning

In some institutes of higher education, much has been made of the increasing absenteeism of students because of professors and instructors being able to distribute their lectures in digital format. Some instructors see this loss of students in a physical building as anathema to their understanding and perception of themselves as teachers. With so much of the face-to-face classroom experience enhanced by myriad ways of gaining feedback from the class, from laughter to subtle signs of discomfort, the instructor loses the opportunity, in some respects, to modify the presentation of concepts to his or her students. For example, an instructor who is speaking about a social networking site on the Internet as a tool for research may have his or her lecture interrupted by a comment from a student who may be aware of a similar site that the professor could then include in future lectures or use to forward his or her own research agenda.

Assessment and Shifting Strategies

One of the most common features of any sort of educational interaction is the ability of the instructor to perform either summative or formative evaluation to determine whether students have understood the concepts of the course. In a face-to-face teaching environment, instructors conduct performance evaluations informally or through assigned projects, whereas summative evaluations are usually the domain of the pencil-and-paper test for examination.

In the online distance learning environment, one of the earliest implementation issues to arise reflected the difficulties of assessing work done by students beyond the scrutiny and gaze of the instructor. Responses to the difficulty of determining whether the students' work is their own have gone in two directions. One way of reducing the possibility that students might share answers is for instructors to provide limited timed testing situations whereby students have only one opportunity to answer questions.

Such tools and techniques to restrict the possibility that students will do summative evaluations in concert with their classmates have their place. However, other instructors have taken a different and potentially transformative approach in response to this problem. That approach has been to change the nature of the assignments students are doing in class. The changes have used many of the tools and affordances of the distance learning environment and course management system employed. Responses to the issues related to assessing learning have led to a major shift in pedagogical models.

Collaborative Teams

One of these transformational changes in pedagogy has been the development of collaborative teams in which students work on a project together online and evaluate each other's contributions to the sum total of the project. The overarching concept behind this approach is that in order to accomplish the project, as a team, members needed a full conceptual grasp of the core concepts. Students would then demonstrate this understanding of the concepts through methods incorporating higher-level thinking skills. Simple restatement of basic facts, which may have been a standard feature in a face-to-face classroom, is a technique that instructors are replacing with project-based activities involving synthesis of new material, evaluation of the work of others, and activities typically associated with complicated thinking tasks.

The Role of Community in Distance Learning

In distance learning, two opposing pedagogical perspectives have had an impact on instructional design: symbol processing and situated cognition. With symbol processing, the teacher transforms abstract ideas into concrete images that he or she presents to the learner via some sort of medium such as television, radio, or the Internet. The job of the learner is to perceive, decode, and store the information from the concrete images.

With situated cognition, the student interacts with both the problem and the construction of a solution to the problem. Students engage in a process of inquiry and draw conclusions from that process. Instructional

designers develop presentations that enable learners to construct new knowledge by interacting with the instruction.

In some respects, distance learning recreates the teacher–student interaction of a face-to-face classroom, but it does so through either synchronous or asynchronous means. Although generally considered primarily asynchronous with the occasional synchronous interactions through a variety of technological means, recent studies have suggested that one of the better models for distance education includes some face-to-face teaching and direct interaction with students. Instructors can effectively place this face-to-face interaction at the beginning of the course or spread it throughout. The physical interaction with students allows the online instructor an opportunity for rich feedback and encourages a more robust learning community.

Virtual learning communities, facilitated by the instructor, increase interactivity between teacher and student and encourage students to interact with each other and with the course content in the online environment. In the case where many thousands of miles separate students, instructors can use inexpensive technological tools to encourage the sense of a learning community.

Lifelong Learning and Distance Education

Although the traditional perception of distance learners is that of the university student or adults engaged in lifelong learning, there are many interesting forms of distance education occurring at the elementary and middle school levels of education. Mostly these are in the form of enrichment activities or telecommunication projects involving the entire class. There are many online sources for projects such as these if teachers were to express an interest in participating. Some projects make use of televised instructional sources, whereas others are entirely text based through electronic mail or through the Internet. Recently, students at this stage in their education have participated as data gatherers in a larger network of students, sometimes global in nature, engaged in discovery projects.

At the secondary school level, rural classrooms and small school districts are making use of distance education courses to help students take advanced placement courses that their school district is not able to offer because of limited enrollment or funding. Educators can also offer these opportunities for taking courses outside the core curriculum in areas such as vocational education or foreign language to students who are not able to attend school because of a disability or because they have chosen to be homeschooled.

One concern that some educators have recently raised is that the boom in distance education may disenfranchise students lacking the skills of self-motivation and discipline. The availability of technological tools enabling the growth of distance learning does not ensure that instructors are well trained either in the development of online courses or in their delivery. Although a high level of interactivity with students can overcome deficiencies in some online courses, some states have considered mandating that at least one online course be required for graduation. In this way, students will gain familiarity with distance education methods and delivery systems, a method of teaching they will undoubtedly encounter in their lives beyond high school.

Digital Literacy

Although television and the Internet can motivate students and stimulate an interest in learning, exciting visuals may serve to focus students' attention more on the form than on the message and underlying meaning. This concern has led to much discussion about the necessity of developing a new kind of literacy in which students are able to distinguish between fact and persuasion, between valid information and propaganda, and between reliable sources and biased opinion. Educators have begun calling this phenomenon *digital literacy* or *Internet literacy.*

Advantages and Disadvantages

There appear to be as many advantages to distance learning as there are disadvantages for each of the stakeholders involved. For students, distance learning renders distance from training centers less relevant. Distance learning has flexibility, accessibility, the ability to create a self-paced learning environment, and less wasted time. That said, there is a loss of direct interaction with the instructor and classmates, a potential loss of immediate feedback, the risk of a higher rate of failure, no access to a physical library, and the potential limitations of the student's own computer system.

For the instructors, there is the possibility of a larger audience, less classroom repetition, more time available to upgrade the course, and the acquisition of

a new teaching experience. However, distance learning changes the dynamics of the classroom environment, there is no visual contact with students, it is sometimes difficult to evaluate students' work, and there is a huge workload at the beginning of the course.

For the institution, there is no need for a physical building, there is potential for international clientele, and the possibility of additional income streams. However, the institution may be in a position to have to reevaluate how it grants credits, it may have to redefine the role of the professor's duties, and it may have to define the rules and procedures for online courses. Additionally, the institution must police an increasingly complex environment regarding copyright and digital rights management.

Distance Learning 2.0

Distance learning is turning a huge corner as scholars and nonscholars alike are using newly emerging social networking tools. In the most recent versions of distance learning, instruction held within classrooms is gradually shifting toward classes conducted virtually, within a computer-mediated communication environment. What is happening now is a steady shift toward learning beyond the classroom in ways that we might excuse the most forward of thinkers for not envisioning.

Sometimes referred to as *e-Learning 2.0* or the *read/write web*, with social networking tools requiring almost no specialized software such as blogs, wikis, and podcasting, the nature of distance learning is transforming. It is moving from the formal model of the instructor in charge of a curriculum to that of an informal gathering of like-minded researchers, both professional and amateur, communicating with each other through direct dialogue or through a trail of references. Using any of a large range of tools, students, classes, or even whole departments can add tags to articles found online and store these tags as links to the articles in such a way that they can share their finds with their larger community of scholars.

The use of interactive blogs creates a social network that moves beyond the very concept of what a course is and can move learning to a place beyond the classroom and even beyond the structured curriculum. Even within a structured curriculum, online blogging tools, with their capability of allowing comments, will enable outside experts to add comments and insights to transform and increase the potential

for enrichment to the distance learning environment. Such tools support increased feedback from instructors, but there is even greater potential for the development of community-centered instruction. Such tools move education from theoretical notions about social cognition and the development of communities of practice to concrete experiences for teachers to create online learning communities.

Of course, the educational interactions do not simply occur without planning on the part of the instructor. Despite the increased participation by all but the most reluctant students to participate in class discussions in an online setting, there is still a need to set guidelines and provide educational leadership and facilitation.

The tool known as a *wiki* enables many users to add to a base of knowledge drawn from their own research and investigations into a topic. Instructors can add a line or two of information with a link to an outside reference source that students can then modify and inform with many other additional sources. This knowledge construction is more actively engaging than other, more passive forms of pedagogy. With the advent of new online tools, such wikis are becoming commonplace classroom tools in the distance learning environment.

Divergent Thinking

Creative thinking is often dichotomized into thinking that is convergent and thinking that is divergent. Of the two, convergent thinking is much simpler to measure and operationalize, whereas the latter, a cognitive process that engenders a variety of novel and unconventional products, has proven far more difficult to model, measure, and predict. To address the complexity of this difficulty, it may be helpful to clarify what divergent thinking is not. By framing a discussion of divergent thinking upon a theoretical delimitation of convergent thinking, one may develop a firmer foundation for a description of cognitive processes that are, by negative comparison, divergent.

The objective of convergent thinking is to generate a conventional, consensually agreed-upon solution to a problem. The problem presents as an initial triggering mechanism or process input—be it a test prompt, an assignment question, or an event—that generates the production of a correct or an incorrect problem solution. Convergent cognitions, therefore, are necessarily goal-directed, and thinking tends toward a linear, serialized sequence of subprocesses channeled via feedback mechanisms such as task monitoring, evaluation, and output verification. Traditional models of the creative process, such as Graham Wallas's *Preparation → Incubation → Illumination → Verification* and John Dewey's *Difficulty Felt → Difficulty Defined → Information Surveyed → Solutions Suggested → Outcome Considered* reflect a deep-structure supposition that creative thinking is a linear, goal-directed process of solving a problem. In addition, to the extent that the goal of convergent thinking is to achieve objectives external to the thinker—that is, success and failure are not based on internal, personal criteria, but rather success is based on the opinions, judgments, and preexistent correct solutions of external agencies—affective engagement with the problem to be solved may, at least initially, tend toward an extrinsic rather than an intrinsic basis for individual motivation and problem relevance.

In contrast to convergent thinking, divergent thinking does not rely on a problem input to initiate cognitive process. A sculptor may "seek" a form in the grain of a block of marble or a poet may "chase" the meaning of a memory triggered by a chance image that then initiates clusters of associated images, memories, and word sounds. These associative clusters (conscious and otherwise), domain-specific facts, procedures and concepts, chance discoveries, environmental intrusions, and dynamical process changes need not work in a serialized fashion, but rather, subsystems may parallel process in simultaneity. As a result, in order to be successful, the divergent thinker has to remain sensitive to competing, often chaotic interactions while maintaining the cognitive equilibrium necessary to generate a coherent artifact.

The above description suggests that divergent thinking processes engender an artifact that is, in a sense, an emergent by-product of thinking, not the end product of problem solving. Indeed, this product as by-product paradigm implies that divergent production, unlike convergent production, renders impossible the prediction of a final outcome or the prospect of recreating cognitive and affective processes back to an initial impulse. Another way to consider this phenomenon is, as the divergent thinker creates, that which she or he creates affects and changes the creator, which in turn affects and changes that which is created. A definition of divergent thinking, therefore, must take into consideration the following subconstruct: Divergent thinking is simultaneously and reciprocally a creating process and a learning process. Finally, apropos to the affective domain, if divergent thinking has the capacity to be internally triggered, and ideas are accepted, rejected, and integrated as guided by personal, internal, intuitive proclivities, then process-associated intrinsic motivation may play a greater role in divergent thinking than it could, comparatively, in convergent thinking.

To summarize, divergent thinking is a complex, associative process of bringing alternative, novel, and unconventional ideas to emergence through activating and accessing both conscious and subconscious subsystems and processes. Herein, the production as by-product construct is characterized by two attributes: First, the act of creation imparts learning-induced change upon the creator, and second, divergent thinkers use an open-ended, often chaotic process of seeking and discovery in contrast to a closed-ended, consciously task-monitored, linear process of solving and answering.

Putting aside recognized issues of discriminant validity, construct validity, and interjudge reliability (e.g., how precisely may one determine what is or is not conventional?), that traditional psychometric tests artificially initiate the cognitive process to be measured via problem prompts suggests one hypothesis as to the limited predictive ability of these tests: External prompts may have the effect of negatively influencing the affective domain of creativity and directly inhibiting the very divergent, non-goal-directed seeking processes that many measures of creativity attempt to capture.

DIVERSITY

In the field of educational psychology, *diversity* primarily refers to differences across individuals and groups. In order to talk about differences, there is often an assumption about what is normal, typical, or mainstream. Educational psychologists have been interested in understanding human life by identifying universal tendencies. Diversity is important to this task because it is the concept through which hypothesized human universals might be better understood. For example, an interest in diversity helps psychologists understand why there is patterned variance across individuals and groups given particular hypothesized explanations for cognitive development. Steele's important work on stereotype threat has explored how performance (including cognitive tasks) can be influenced by social stereotypes. Because

social stereotypes work off of, and reinforce, social expectations for groups of people (by race and gender, for example), diversity is an important theme.

In mainstream educational psychology, it is rare to find the word *diversity* in the index or in a chapter title. Its position in educational psychology is somewhat indicated by that fact. It is, nonetheless, not a totally invisible concept. Diversity has found its way into educational psychology because researchers are interested in the ways in which society and social forces influence the individual. As such, racial and gender diversity as social forces, for example, have gained the interest of educational psychologists. Moreover, concern for social justice and attempts to understand social phenomena such as violence and prejudice have led educational psychologists to look more closely at social diversity. There are four trajectories in educational psychology in which concepts of diversity have become of vital interest. Each of the five trajectories, described below, implies slightly different emphases in the definition of *diversity*. They are presented below following a rough historical chronology, but the reader should realize that these conceptions of diversity have influenced and affected each other and can all be seen in contemporary educational psychology.

In the first place, psychologists are interested in developing theories and research explaining and describing human universals. Although educational psychologists tend to be attentive to individual differences and deviations, the idea of "human" was not socially complicated. There were many assumptions of universality left unquestioned in the research designs and theories. For example, Kohlberg initially studied "human" moral development by examining only men, assuming that men and women were the same. Thus, diversity enters the scene of educational psychology as a way of identifying greater complexity in human phenomena by questioning the assumptions of universality. Researchers' capacities to understand human universals and make claims that best represent the population to which they are generalizing are strengthened when those researchers question the universal assumptions at the outset so that those assumptions are not blindly built into research designs and theories.

This change in the field led to including diversity as a potential feature of the research design in educational psychological studies. In this second trajectory, *diversity* is a broad term covering a range of discrete variables. These variables generally reflect the attitude,

scope, and place of diversity within the field of educational psychology. The variables in educational psychology that are most often linked to the concept "diversity" include, for example, race, gender, culture, and sexuality. Categories of diversity entered the research of educational psychologists in this way. A person's social experiences of race, gender, culture, and so on have been found to affect personal psychological phenomena. For example, Clark and Hatfield have reported differences in receptivity to sexual offers among college-age students based on gender. Studies will now typically report the racial and gender characteristics of their subjects even if their findings are meant to generalize more broadly and even if these social categories are not considered variables in the study. This allows the readers of the research to consider the role of diversity in the research design. The term *diversity*, here, refers to a set of social categories within which one can subdivide people into easily identifiable groups. This has been a very important trajectory in educational psychology because it allows us to explain patterns of difference across humans in order to better understand potential human universals and their deviations as they are relevant for education. The tendency in educational psychology is to explain deviations from human universals as a function of individual differences. As a result of this trajectory, educational psychologists developed interests in topics such as gender identity development, homosexual identity development, and the effects of poverty on development.

Third, psychological concepts of the "individual" became more complicated in educational psychology through the notion of group membership. Relevant categories of diversity involved distinguishing groups from one another. This became an important departure in educational psychology, where developmental models of human characteristics have had a broad and enduring impact on psychologists' conceptions of humans. With developmental models, age and stage constitute primary categories of internal difference, but these are not conceptualized as characteristics of one's membership in a social group. Tajfel and Turner began studying something they referred to as social identity. *Social identity* is a composite of three aspects—social group categorization (including self-categorization), self-identification with a group, and social comparison with other groups. Social identity theory and findings suggest that groups are not just something externally constructed around individuals, but instead reflect something inherently constitutive of individuals' claims

about themselves. In other words, Tajfel and Turner piqued the interest of educational psychologists in investigating the possibility that individual differences did not necessarily precede group memberships and affiliations. When seen as variables, the characteristics of diversity are theorized as external to human universals and individual characteristics, but nonetheless descriptive and interesting for understanding psychological phenomena, such as responses to attractiveness. With this second trajectory, diversity across groups is fundamental to both the sense of group identity and the sense of uniqueness that individuals will claim about themselves. The term *diversity* here contrasts with sameness. This trajectory has led to a lot of research on ethnic identity, ingroup/outgroup phenomena, and psychology of gender, and it has likewise influenced the ways educational psychologists include diversity in their research and theorizing.

Fourth, the concepts of diversity are relevant to the research on intergroup relations, including ingroup/outgroup behavior, scapegoating, stereotype threat, prejudice, and other theoretical/empirical phenomena. In these cases, diversity reflects the notion of difference between groups as well as attitudes and responses to those differences, including attitudes and responses that are influenced by majority/minority relations. Categories of diversity are not mere variables for this body of work, but rather diversity itself is at the heart of the social phenomena of interest. There is no way to understand the basic concepts of intergroup relations, including the above list of phenomena, without the concept of diversity as indicative of group difference. For this work, diversity is most often conceptualized as interindividual differences.

Following World War II, during the rise of social psychology in the United States, studies on conformity and authority were complemented by studies on ingroup/outgroup phenomena and scapegoating. These latter interests sought explanations for the Holocaust through ideas that depended on intergroup and interindividual differences. Studies that indicated the force of arbitrary group affiliation on ingroup/outgroup behavior and preferences led researchers to investigate the not-so-arbitrary group affiliations at work in people's everyday social lives. Much current research and related theoretical ideas have emerged from this trajectory. For example, Steele launched a very important set of contested studies on stereotype threat. These studies examine the extent to which a person will underperform when his or her social group is negatively

stereotyped. The term *diversity* here refers to differences across groups and the social ramifications of those differences when social power is also evidenced. Aronson developed a popular educational tool for mediating the negative consequences of group differences and magnifying the social value of those differences—he referred to this as the Jigsaw. With both Steele's and Aronson's work, social psychology has become engaged in the critical efforts to address the negative social impacts that inequality across diverse social groups has had on society as a whole and most particularly on individual members of society.

Finally, in contrast to the move toward interindividual differences, there is a postmodern approach to educational psychology reflected in the work of Gergen. This trajectory appropriates the ideas of diversity to explain that intraindividual phenomena are influenced by diverse social forces. Gergen takes social identity theory in a different direction by arguing that any one given individual identifying with any number of social groups—with equally many stereotypes, perspectives on truth and experience, and so on—becomes "saturated" with diversity from the inside and the outside. Moreover, Gergen specifically attributes the patterned changes in intraindividual psychology to the increasingly complex and diverse social world. Gergen's approach is differently empirical. Gergen acknowledges forms of evidence not traditionally accepted within the field of social psychology; these new forms of evidence include such cultural products as films and artifacts. Gergen argues against the idea that people's minds represent or reflect the external world. The diversity of the external world does not solely influence individuals nor vice versa, but instead, the internal and external worlds are integrated in complex and contested ways. The image such ideas produce is more akin to a collage of interindividual and intraindividual diversity rather than a dichotomy. The emphasis on diversity as "perspectives" is most relevant for postmodern and poststructuralist social psychological work. From this way of thinking, the term *diversity* here refers to the multiplicity of truth claims authentically and sincerely asserted from across and within individuals as persons and as members of complex social groupings.

These more recent trends in the way diversity is conceptualized in educational psychology reflect a more critical tendency in educational psychology than was evidenced in its early days. Empirical findings and theoretical developments are linked to efforts to answer social problems so as to improve the psychological life conditions. The five trajectories in which diversity is found relevant to educational psychology also then reflect a history of educational psychology. Taken all together, we see diversity largely referring to group-related differences that have both inter- and intraindividual points of interest. Across the trajectories, there is a broadening of how diversity is conceptualized, moving from the idea that diversity was the sum total of individual differences across human universals toward the idea that it was a social phenomenon that transcended individual difference while also involving it.

DIVORCE

Divorce is defined as the legal dissolution of a marriage. As a legal action, divorce culminates in a final

divorce decree, which outlines for each individual his or her obligations for division of property and assets; support, if indicated; and provisions for children. Separate from legal implications, divorce is a transition that implies logistic and psychological challenges for all involved. Common challenges for adults going through the divorce process are processing grief, restoring self-esteem, managing anger, and easing emotional pain for their children. Common tasks for parents going through the divorce process are developing an identity as a divorced parent, becoming an effective single parent, dealing with their child(ren)'s anger, and establishing a workable co-parenting relationship with their ex-spouse.

Divorce is important to educational psychology because it is associated with family and child factors that have an indirect effect on children's educational outcomes. Thus, this entry focuses on divorce within the context of families with young children. This review first provides a brief, recent historical overview of divorce in the United States. This is followed by highlights of typical child divorce effects, as well as developmentally specific child divorce effects. Finally, the impact of divorce on the learning environment is presented, with a focus on school-based programming to support children and families.

Historical Overview

The divorce rate rose from 0.3 per 1,000 population in 1967 to its highest rate of 5.3 per 1,000 population in 1979. The change in social attitudes related to modern urbanization, including increased education and employment for women combined with smaller numbers of children per household, and the change in legal guidelines that allowed for no-fault divorce primarily account for this considerable change.

Currently, 51% of all U.S. marriages end in divorce. Often, children are involved, and more and more families with the youngest children are finding themselves in the predicament of divorce. For children who experience the divorce of their parents before age 12, at least two thirds experience it by the time they are 6 years old. Of all children who experience the divorce of their parents before the age of 6, 40% do so in the first year of life, 20% between 1 and 2 years, 15% between 2 and 3 years, 10% between 3 and 4 years, and 15% between 4 and 5 years. Thus, divorce is a common occurrence in the lives of infants, preschool, and early school-age children.

Specific to the context of divorcing families with young children, the judicial system has had the task of considering divorce in the context of children's best interests. This focus dates back to the 19th century, when it was initially legally specified that children have rights independent of their parents. This assumption was the basis for the later "best interests of the child" principle. The term was coined in the 1925 *Finlay v. Finlay* case and places judicial officers in a parental role to the family, determining what scenario best suits the needs of a given minor child. During the early 1900s, the realm of parenting responsibility was predominantly determined by gender, with mothers being responsible for nurturance and fathers being responsible for discipline. The general consensus in a divorce proceeding resided in a mother's parenting role carrying greater weight for children's development than the father's. As a result, the majority of residence decisions placed children with their mothers. This earlier approach was mirrored in the 1970s with the Uniform Marriage and Divorce Act, which emphasized the emotional needs of children in the "tender years" as being best served by residing with their mothers. This presumption has been scrutinized for its unconstitutionality and has gradually been replaced by a case-by-case review among judicial officers applying the best interests of the child principle.

Currently, the principle primarily pertains to decisions about child residence and parental access. These decisions are established in the form of parenting plans with outlined parenting time responsibility. What remains the same is the aim of the principle, which is to reduce the concept of parental ownership of children and minimize a competitive stance in litigation, with resulting judicial decisions articulated based on children's needs rather than parents' rights. The basis for understanding what is in children's best interests has evolved out of collaboration between the legal and mental health professions. Specifically, between 1973 and 1986, and revised in 1996, the principle encompassed the idea that custody decisions should both safeguard the child's need for continuity of relationships while reflecting the child's sense of time. Some states used a criterion set forth in Michigan as a check against this conceptual definition of the best interests of the child principle. For the most part, however, states have used case law to guide decisions about child residence and access.

Regardless of the availability of identified criteria or case law used to normalize the best interests of the

child principle, the lack of empirical research has limited its application. Namely, without empirical research as a guide, the application of the best interests of the child principle has been fraught with difficulty and fodder for individuals involved in residence and access disputes, formerly known as custody disputes, to manipulate its intent for their purposes. In particular, individuals involved in high-conflict divorces, often centered on children and assets, express the needs of their children predominantly in terms of their own needs.

High-Conflict Divorces

Although divorce presents challenges for all children, particular family dynamics associated with high-conflict divorces have been shown to influence child outcomes. How and to what degree of success parents negotiate their continued relationship has been found to have a significant impact on young children's post-divorce adjustment that is quantitatively and qualitatively different from other divorce factors. Within this renegotiation, the way parents communicate with each other, especially the conflict resolution strategies they use, is particularly important. Because of its reciprocal nature, these communication patterns include both communication behavior and interpretation of verbal and nonverbal cues by the other parent.

At the same time, divorce is often considered to be contentious by nature. Although some divorces are amicable, many are not. Thus, it is important to establish what constitutes a type of communication and a level of conflict associated with negative postdivorce child adjustment. Low levels of conflict and high levels of communication optimally meet the best interests of the child principle observed by the legal community for child residence and parental access decisions. The reverse has also been found to be true, where high levels of conflict in families with shared parenting responsibility result in poor adjustment outcomes for children. In particular, children of high-conflict divorce display behavioral, cognitive, emotional, and social problems to a greater degree than do other children from separated or divorced families.

Typical Child Effects

Typical child effects include feelings of sadness, anger, and fear, which may manifest in behavior changes and/or emotional and behavioral problems. It is common for these problems to become evident in the school setting. Typical in school-age and adolescent children is the desire or fantasy for parents to reunite, fear of abandonment by one or both parents, and/or feelings of responsibility for the divorce.

Infant/Toddler Age

Children express their difficulties in the area where they are currently developing. Several developmental theories suggest that infant and toddler-age children experience significant effects of divorce. Common behavioral manifestations in infant/toddler-age groups are increased crying; intensity of problems separating from either or both parents; regression to an earlier developmental stage, especially in toileting; and sleep problems.

Attachment is considered the most significant socio-emotional developmental milestone for the infant/toddler-age group. According to attachment theory, it is important to build an attachment to a primary caretaker. Thus, the risks associated with divorce for this age group are related to attachment formation. These risks include feelings of loss of contact with the primary attachment figure, resulting in child depression and regressive behavior, as well as separation and relationship difficulties in later development. The risks inherent to separation from the primary caretaker for extended periods may affect current development and also threaten the foundational task of attachment formation and subsequent developmental tasks. Attachment theory assumes that the quality of attachment is closely linked to caretaker sensitivity to the child's needs. One concept related to this assumption is the notion of the effect of these interactions over time in development of internal working models of attachment. Essentially, relationships with caretakers greatly influence the child's way of thinking about new people and experiences. Thus, attachment quality is considered an important link to later development.

School Age

The majority of research on divorce effects in children has been aimed at child adjustment in school-age children. These studies have commonly focused on cognitive effects, such as school performance, and psychological and social functioning, including behavioral problems. At this age, cognitive ability increases, including the ability to take another's

perspective. More specifically, the recognition of other people's feelings and goals, a more sophisticated type of reciprocity, is closely intertwined with cognitive ability in perspective taking. As a result, a couple of common behavior manifestations present themselves during this period for school-age children of divorcing parents. School-age children often feel anxious out of concern over loyalty to their divorcing parents. Also common at this age are feelings of anger that come with the lack of control they have over their current situation. The initiation of school-home communication and newly presented homework responsibilities pose a unique and additional challenge for these children as they frequently move between both parents' homes.

Adolescent Age

Adolescent children experience many of the same emotions that younger age groups do, but manifest them in different ways. One of the recognized adolescent milestones is the expression of a need for independence. Within the context of experiencing divorce within their families, adolescents may exhibit an effort to control their situation by demanding and then changing living arrangements with each parent. Because of the tendency toward risk-taking behavior in this age group, this can present challenges in potential negative risk-taking behaviors.

School Supports

Families embroiled in high-conflict divorces as well as typical divorcing families may be overwhelmed with both logistic and psychological challenges associated with divorce. In this way, school personnel educated about typical and age-specific divorce effects can support the detection of divorce effects and aid in intervention. Although all children experience divorce differently and in their own time frame, as has been noted, there are typical divorce effects found in children from divorcing families. These effects include feelings of sadness, anger, and fear, which may manifest in behavior changes and/or emotional and behavioral problems, and it is common for such behavior to become evident in the school setting.

School supports include adult and peer support and support of home-school communication. Adult support can be provided in the form of school counselors or other trained professionals. These individuals can help children to understand the divorce process and develop coping skills. As divorce becomes a typical social stressor for school-age children, schools are more frequently providing peer-based programs for children from divorcing/divorced families. Facilitated peer support groups have the effect of normalizing the divorce process for children. This can help children to reestablish a sense of personal control. Additionally, school personnel, including teachers, can support children from divorcing/divorced families in managing home-school communication. This type of support can be provided by way of considering binuclear families' special needs, such as when children go between two homes, as they pertain to home-school communication. This is a particularly important support to the child in the early stages of divorce, when levels of interparental conflict are typically higher and levels of positive interparental communication are typically lower.

Domestic Violence

The ways in which domestic violence is defined vary as much as the people who are the perpetrators and victims of domestic violence. Broadly speaking, domestic violence can refer to any verbally or

physically aggressive act committed within the context of a close interpersonal or familial relationship. This definition would include violence perpetrated from a husband against a wife, an adult child toward his or her mother, or even aggression between siblings. However, domestic violence more commonly refers to physical or psychological aggression committed by an intimate partner such as a husband, wife, girlfriend, or boyfriend against another intimate partner. Because of the prevalence of domestic violence in society, professionals are increasingly being confronted with the problem in schools, the legal system, and the workplace.

Prevalence

Estimates of the prevalence of domestic violence vary for a number of reasons. The violent acts that are frequently considered domestic violence can range from psychological abuse to sexual abuse. Psychological abuse typically refers to such things as insulting, swearing, or yelling at one's partner; stomping out of a room; saying something to spite one's partner; calling one's partner names; destroying something that belongs to one's partner; or threatening to hit a partner or throw something at him or her. Moderate levels of physical abuse can include actually throwing objects, twisting a partner's arm or hair, pushing, shoving, grabbing, or slapping. Severe physical abuse is normally characterized by use of a knife or gun, hitting with something that could hurt, choking, slamming against a wall, striking with a closed fist, kicking, or sexually assaulting a partner. The prevalence of domestic violence generally increases when less severe acts are included in the definition and decreases when only the most severe forms of domestic violence are included. Prevalence estimates also can vary because of the people who are sampled. Domestic violence occurs more frequently in couples who are unsatisfied in their relationship, couples who seek counseling, and among women seeking assistance at domestic violence shelters. Estimates also will vary depending on whether they are based on self-reports given over the phone, offered anonymously in a research setting, or based on actual crime statistics.

As a result, estimates of the prevalence of domestic violence vary across different groups. About one quarter of women report experiencing some form of physical or sexual violence at the hands of a romantic partner at least once in their lifetime. Probably about

10% of women will experience some form of severe violence, and women are more likely to be murdered by an intimate partner than by anyone else. Furthermore, more than 10% of women who are married or cohabiting report being physically abused annually, approximately 1 million each year. Of course, domestic violence is not only confined to married or cohabiting couples. The majority of high school and college students report being involved in an aggressive or violent relationship. Domestic violence also is not only confined to male-female relationships. Domestic violence occurs in heterosexual couples and homosexual couples, and evidence is increasingly suggesting that women also perpetrate domestic violence against men. Although domestic violence is not confined to heterosexual couples where the man is the perpetrator and the woman is the victim, most of the research focuses on these types of relationships. As a result, this discussion also primarily focuses on the male perpetration of domestic violence in heterosexual relationships unless expressly noted otherwise.

No matter the precise figures regarding the prevalence of domestic violence or even the nature of the relationship, it is clear that there are significant societal costs associated with domestic violence. A significant percentage of emergency room visits by women are the result of domestic violence, and women in abusive relationships are more likely to visit their family physician for a host of physical complaints, many of which are directly related to the abuse. Domestic violence calls are among the most common job-related tasks for law enforcement officers across the country. Men who abuse their partners also are more likely to abuse their children and in turn negatively affect their children's socialization and academic performance. Nonetheless, domestic violence cuts across all occupations, races, and socioeconomic groups. No person is immune from being a victim of domestic violence.

Risk Factors

Although domestic violence cuts across different groups, there are factors that increase the risk for the perpetration of domestic violence. These *risk factors* can be grouped into demographic, psychological, and contextual variables. The most relevant demographic factors typically include variables such as age, socioeconomic status, and race.

In general, the younger the perpetrator of domestic violence is, the lower the risk for committing

domestic violence. These age-related declines are even greater for more severe violence compared to moderate levels of domestic violence. Even though the wealthy, middle class, and poor are all victims and perpetrators of domestic violence, the lower one's socioeconomic status, the greater the risk for domestic violence. This increased risk is normally related to the additional financial and social pressures as well as the reduced social support and education more likely to occur in lower socioeconomic groups. The role of race and ethnicity has a complex relationship as a risk factor for domestic violence. Normally, perpetrators who are African American, Latino/Hispanic, or generally of minority status are at greater risk to perpetrate domestic violence. However, it is important to examine other factors that might be the cause of this relationship. Specifically, socioeconomic status appears to be related to race and ethnicity and may be the real reason for the increased risk within many minority groups. It is not simply that many minority groups are more likely to perpetrate domestic violence, but that they are more likely to be unemployed, live in poverty, be less educated, and work in lower-status occupations that are all related to a reduced socioeconomic status. When socioeconomic status is factored into the equation, race is not related to the perpetration of domestic violence.

Another category of risk factors commonly identified for the perpetration of domestic violence is psychological risk factors. Obviously, men who are more hostile and angry are more likely to perpetrate domestic violence. Surprisingly, though, men who are less assertive are also more likely to be violent. Assertiveness should not be confused with aggression. Assertiveness is the ability to appropriately express your feelings or ideas in a social situation, especially when those feelings or ideas may be met with resistance or are in the form of a request. Men who are more likely to perpetrate domestic violence have difficulty expressing themselves in an appropriately assertive manner and therefore often resort to violence or aggression out of the resentment they let build up. A lack of self-esteem is often related to poor assertiveness and in turn is also a risk factor for domestic violence perpetration. Another risk factor for domestic violence that will be examined more closely later is the need for power and control. Traditionally, treatment programs for domestic violence perpetrators focus on the need of the perpetrator to dominate and control his victim, and violence is one mechanism for him to do so. In addition to these

less pathological psychological risk factors, there also is a relationship between domestic violence and particular psychological disorders. Depression and other personality disorders, such as borderline personality disorder and antisocial personality disorder, have been consistently linked to domestic violence. An even stronger risk factor for domestic violence is the use and abuse of drugs and alcohol. Evidence suggests that not only are perpetrators of domestic violence more likely to suffer from a substance abuse disorder, but they are more likely to abuse alcohol or drugs immediately prior to the abuse itself.

The final category of risk factors related to domestic violence is the group of factors related to the relationship or the environmental context in general. Overall, it is very clear that perpetrators of domestic violence are more likely to be dissatisfied in their romantic relationship and that relationship dissatisfaction may be one of those most significant risk factors for domestic violence. This dissatisfaction may be evident in more disagreements or bickering or simply an emotional distance between the couple.

Another variable that may be somewhat surprisingly related to an increase in the severity of domestic violence perpetration is pregnancy. There may be a host of reasons for this risk factor, including additional dependency of the mother on the father, additional stress and financial commitments, and insecurity on the part of the father because of the change in their relationship. Other significant risk factors for the perpetration of domestic violence are related to childhood experiences. A child who is the victim of child abuse or witnesses domestic violence between his parents is at greater risk for the perpetration of domestic violence. This relationship is sometimes referred to as the intergenerational transmission of violence. The intergenerational transmission of violence refers to the fact that children who live in abusive relationships are more likely to perpetrate abuse as they become adults, enter into their own relationships, and thereby expose their children to abuse, which continues the cycle of violence.

Risk Assessment

Identifying risk factors for domestic violence is important for the assessment, prediction, and prevention of domestic violence. The term *risk assessment* refers to the formal evaluation of the potential risk that a perpetrator of domestic violence poses to

commit future domestic violence. Although risk assessments used to be satisfied with predicting the probability of future domestic violence, they are now concerned with much more than just the likelihood of future violence. Risk assessments also should evaluate other aspects of the future violence, such as the potential timing and severity of the violence. Risk assessments should rely on multiple sources to collect this information. It is not sufficient to rely only on the perpetrator for information but instead legal records, witnesses to the violence, and mental health records should be consulted. Most importantly, the risk assessment should be victim informed. The victim should be an integral component of any risk assessment of the perpetrator because she is likely to have a perspective that no other single person can provide. Finally, risk assessments should focus not only on assessing risk but also on managing it. *Risk management* refers to the process by which an attempt is made to reduce or avoid domestic violence. For example, part of the risk management process may be to refer the victim to a domestic violence shelter or encourage the perpetrator to seek psychological treatment for his domestic violence problem. Treatment for both the perpetrator and the victim are central to effective risk management.

Treatment and Intervention

A variety of interventions have been designed to manage or treat domestic violence. However, no single intervention will prevent all domestic violence or even most violent incidents. The best intervention is one that is multimodal or uses multiple approaches to solving the problem of domestic violence. Accordingly, the prevention and cessation of domestic violence can be accomplished only through the use of psychoeducation, community involvement, and the criminal justice system.

Psychoeducational Interventions

Psychoeducational interventions tend to focus on the men as perpetrators or women as victims, or on couples. The more traditional psychoeducational approaches to domestic violence focus on men as perpetrators. Typically, these programs are either feminist oriented or cognitive-behavioral, or a combination of the two. Traditionally, treatment programs have had a feminist orientation that encourages men to examine

their adoption of certain patriarchal messages within society. For example, the feminist model suggests that the cause of domestic violence is the power differential between men and women that modern society supports. The approach argues that men commit domestic violence in an attempt to dominate and control their female partners, as they have grown up in a society that encourages women to adopt a subservient role. The feminist model argues that only through recognition of this role and a rejection of it can domestic violence stop. The cognitive-behavioral model tends to focus on anger control and suggests that men perpetrate domestic violence largely because of certain aggressive supportive thought patterns they exhibit. For example, a perpetrator may think that his wife *never* listens to him, and that he can either continue to be ignored or become violent so she listens to him. Cognitive-behavioral approaches get perpetrators to identify these errors in their thinking and teach them to replace the thinking errors with more appropriate thoughts that then reduce the likelihood of being aggressive. It is not currently clear that either one of these approaches is superior to the other, but this finding may be because few batterer programs are strictly feminist based or strictly cognitive-behavioral and instead are a combination of the two.

Batterer Typologies and Treatment

As greater attention has focused on treatment interventions for men who perpetrate domestic violence, researchers have increasingly concluded that there is no single type of batterer. The batterer literature generally suggests that domestically violent men can be categorized into subgroups based on individual characteristics such as personality/pathology and the nature of their past violence. It has been suggested that these *typologies* could be useful in designing treatments and identifying the causes of domestic violence. For example, scholars have speculated that batterers with antisocial personality disorder and a history of generalized violence will be the least likely type of perpetrator to benefit from existing forms of treatment. Consistent with this speculation is that batterers who drop out of treatment are more likely to have drug and alcohol problems, and antisocial or narcissistic tendencies. They are also more likely to have committed more severe levels of domestic violence, and their probability of reoffending is elevated. As a result, it is believed that treatment programs for

men that focus on the specific needs of these different types of batterers are likely to improve treatment outcomes and increase the effectiveness of domestic violence treatment for men.

There are also psychoeducational programs designed to treat women, both as victims and as perpetrators. Traditional approaches focus on treating women as the victims by addressing issues related to self-esteem, removing any self-blame or guilt they might experience by incorrectly believing that they are the reason for the violence, and increasing their awareness about alternatives to the abusive relationship. Many people question why women remain in these violent relationships. The reasons are multiple and varied. Women in these relationships are frequently dependent on their partner for financial reasons and unable or unclear how to provide for themselves financially. In addition, the woman may have the added responsibility of being the primary caregiver for the children and may not know where to turn for child care assistance even if she could find employment. Perpetrators also attempt to isolate their victims away from their friends and family and therefore make escaping the relationship even more difficult. The psychological and physical abuse also takes a toll on the victims' self-esteem and belief that there is anything or even anyone outside of the perpetrator for them.

Battered Woman Syndrome

Lenore Walker originally used the term *battered woman syndrome* to explain the abusive relationship and the reasons why many women have difficulty leaving their batterer. Based on her observations with battered women, Walker believed that the violence occurred in cycles of three stages. During the *tension-building* stage, the abuse is largely verbal or very mild physical violence. The victim may attempt to appease the abuser and minimize the seriousness of the abuse. The abuse escalates and becomes the most severe during the *acute battering* stage. The acute stage is followed by *loving contrition.* During this stage, the abuser is profoundly apologetic for his behavior. He may completely change his attitude, shower the victim with attention and gifts, and promise never to be abusive toward her again. Walker believed that women who were repeatedly abused developed *learned helplessness*, based on the work of Martin Seligman. Seligman demonstrated that if dogs were shocked repeatedly without any way to escape the

shocks, they would eventually no longer try to escape even if a way for them to escape the shocks became obvious. Walker believed that the uncontrollable cycle of violence was similar to the inescapable shocks for the dogs. However, besides Walker's observations, there is very little support for the notion that all or even the majority of women in abusive relationships experience the cycle of violence or learned helplessness. Nonetheless, it remains a popular notion among domestic violence advocates, and battered woman syndrome has been used in court as a defense for women who kill their abusers.

Couple Treatment

Two more controversial treatment approaches for domestic violence are treating couples and treating women as the perpetrators of domestic violence. In couples' therapy, the partners focus on each of their contributions to the escalation of the violence when a discussion begins in a calm and rational manner. Although research has found this approach to be effective in some instances, there are many reasons it remains controversial. Some argue that by focusing on each partner's contributions to the violence, it removes responsibility from the real culprit, the perpetrator of the domestic violence, and places blame on the victim, further victimizing her. In addition, some believe that it is inappropriate to treat the perpetrator and the victim together because it encourages the violence and heightens the risk to the victim because she may say something in therapy that she is later punished for outside of the therapy session. Supporters of the approach reply that couples are not suitable for this intervention if there continues to be physical abuse in the relationship.

Interventions that focus on the woman as the perpetrator of domestic violence are also increasingly being used. These treatment approaches typically are cognitive-behavioral in orientation and tend to focus on anger control and other issues, such as trauma, that may be unique to women who perpetrate domestic violence. These approaches obviously conflict with the traditional feminist approach to treatment that suggests that only men can be the perpetrators because of the power differential that exists in our society. The notion that women perpetrate domestic violence is based on more recent but consistent findings in the literature that not only do some women perpetrate domestic violence, but also the perpetration rates between men and women may be equal and the

causes of their domestic violence similar. However, critics argue that even if there are equal rates of perpetration of domestic violence, the violence is not equal in any other aspect.

Many arguments exist that attempt to explain these equal rates of perpetration. First, critics argue that the equal perpetration rates are based largely on self-report data, and the research tends to suggest that men underreport their violence more than women. It also is argued that the violence typically perpetrated by women tends to be in self-defense. Women who act out in violence do so because they are being abused or are about to be abused, and they are attempting to retaliate while they are still physically capable. Another argument is that even if the frequency of the violence is equal, the severity of the violence is not. Men are more likely to perpetrate more severe violence that results in medical attention or greater physical injury because of their greater physical size and strength. Finally, there is a difference between the perpetration of domestic violence and *battering*. Critics argue that women may be able to perpetrate domestic violence, but they are not able to batter. Battering is usually distinguished from perpetration in terms of the severity of physical damage, the ability to socially and financially isolate the victim, and the general difference in the ability to dominate and control the victim. The argument is that men are able to batter women and that the negative effects of battering go beyond physical abuse.

Community-Level Interventions

In addition to the psychoeducational interventions for men, women, and couples, it is also important to have community involvement. Community involvement normally focuses on the use of advocates, shelters, and safe homes. Advocates are professionals who may work for organizations such as the YWCA or local domestic violence councils, or as a part of local government such as a prosecutor or police. Advocates typically assist the victims of domestic violence in navigating the system. This process may mean supporting the victim emotionally and encouraging her that she is doing the correct thing in seeking help for herself and her children, and in leaving her husband. It may mean talking to the victim about the difficulties that are likely to occur in filing criminal charges and prosecuting her partner for assault or domestic assault. Advocates also help victims identify the resources available to them in the community for providing basic necessities and protection if they have left their abusers and were financially dependent on them. One of those resources may include a safe house. Safe houses are places where women and their children can find temporary shelter. They often stay with individual families who are willing to take in women or consist of houses in secret locations so that the batterer cannot find the victim. Shelters tend to be more formalized programs that provide shelter and necessities for the victim and sometimes her children. Shelters may also provide psychological counseling and occupational counseling to assist the woman in living independently.

Criminal Justice Interventions

Another element that is important in preventing domestic violence is the criminal justice system. There are a number of ways in which the criminal justice system can take an active role in the prevention of domestic violence. First, law enforcement officers are increasingly being trained in the de-escalation of domestic violence and some of the subtleties involved in domestically violent relationships. Part of the investigative aspect of domestic violence as a crime is the use of *mandatory arrest polices*. Mandatory arrest policies are common in many major cities and counties. Mandatory arrest policies require an arrest if it appears an act of domestic violence has occurred. These policies were met with initial enthusiasm. It was believed that they would allow for a separation of the perpetrator and victim, result in a cooling-off period, give the victim a chance to escape, and encourage the prosecution of the perpetrator. However, research has failed to universally support the use of mandatory arrest policies, and some research suggests that domestic violence increases once the perpetrator returns. Other policies that can be implemented by prosecutors and judges are the use of restraining orders and no-drop policies. Restraining orders require perpetrators to refrain from any contact with the victim and to remain an identified distance away from the victim. No-drop policies mandate that the prosecution cannot drop the charges against the perpetrator and can even force the victim to participate, even when it frequently occurs that she is unwilling to participate after she has reconciled with the perpetrator.

DRUG ABUSE

The definition of drug abuse has fluctuated with changes in cultural and legal norms, and there is currently no consensus on a standardized definition. However, drug abuse generally can be defined as the harmful or risky use of legal or illegal drugs or the use of legal drugs in a manner or amount inconsistent with medical advice. Some organizations such as the American Psychiatric Association (APA) do not refer to the abuse of drugs per se, but rather to the abuse of substances in general. These two terms (*drug abuse* and *substance abuse*) are often considered synonymous and are used synonymously in this entry.

The abuse of drugs is frequently associated with a myriad of psychosocial issues, including violence, homicide, homelessness, premature death, psychopathology, and economic loss. For secondary school-aged and college-aged individuals in particular, drug abuse is also correlated with school failure, criminal activity, accidents, aggressiveness, unsafe sex, unplanned pregnancy, and suicide.

Humankind has used alcohol and other drugs in one form or another since the beginning of recorded history. Alcohol was consumed as early as the Paleolithic era, and other drugs such as cocaine, marijuana, and opium have all been used in the past for religious or medical purposes. Even today, the abuse of both legal and illegal drugs is relatively commonplace despite moral implications and legal repercussions. Drug abuse is both a major public health issue and a highly pertinent matter facing educators today. Given the reliable association between drug abuse and impaired academic performance (among other variables relevant to students), educators, researchers, and practitioners of educational psychology need to be acutely aware of the following in order to help maximize the performance and adjustment of individuals in educational settings: the costs of drug abuse, trends in drug abuse, gender differences, theories of drug abuse, risk factors for drug abuse, the diagnosis and assessment of drug abuse, treatment options, and issues in prevention. These topics are addressed in this entry.

Costs and Trends of Substance Abuse

Economic Costs

The economic costs associated with alcohol and other drug abuse are staggering. According to the Office of National Drug Control Policy (ONDCP), the overall cost of drug abuse other than alcohol in 2002 in the United States was in excess of $180 billion. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) also estimated that, in 1998, the cost related to alcohol abuse alone was also in excess of $180 billion. In both of these cases, the majority of costs were attributed to lost productivity and health care costs. The ONDCP also reported that in the year 2000, Americans spent an estimated $36 billion on

cocaine, $11 billion on marijuana, $10 billion on heroin, $5.4 billion on methamphetamine, and $2.4 billion on other illegal drugs.

Trends in Use and Abuse

The Substance Abuse and Mental Health Services Administration (SAMHSA) conducts an annual National Survey on Drug Use and Health (NSDUH) of Americans aged 12 years or older, and this is the primary source of information on the use of illicit drugs, alcohol, and tobacco in the civilian, noninstitutionalized population of the United States. According to the results of the 2005 NSDUH, an estimated 19.7 million Americans (or 8.1% of the population) reported using an illicit drug during the month prior to the survey. The most commonly used illicit drug was marijuana (14.6 million users in the past month), followed by prescription drugs used nonmedically (6.4 million), cocaine (2.4 million), and hallucinogens (1.1 million). Slightly more than 50% of Americans aged 12 years or older had consumed alcohol within the 30 days prior to the survey, which translates into about 126 million Americans.

The prevalence of drug abuse in youth should be of special interest to the educational psychology professional, considering that the current rate of illicit drug use among youths aged 12 to 17 within the past 30 days is approximately 11%, that approximately 28% of individuals between the ages of 12 and 20 drank within the past month, and that nearly 19% of them engaged in a binge-drinking pattern (defined as at least five drinks in a day). Researchers at the University of Michigan conduct an annual study on drug use trends among 8th-, 10th-, and 12th-grade students called the Monitoring the Future (MTF) study. Each year, the MTF study gathers self-report survey data from approximately 50,000 students to determine drug use rates and attitudes. According to the 2005 MTF study, alcohol is cited as the most commonly abused drug, followed by cigarettes and marijuana. This trend in alcohol abuse is especially troubling, considering that recent National Institutes of Health (NIH) studies have revealed that young people who began using alcohol before age 15 are four times more likely to develop alcohol dependence during their lifetime than those who began drinking at age 21 or later. Moreover, these youth are seven times more likely to report having been in an alcohol-related traffic accident during adolescence and adulthood.

Nevertheless, in 2006, the MTF study found a 23% reduction in the number of adolescents using illegal drugs between 2001 and 2006, including decreases in the use of marijuana, methamphetamine, steroids, LSD, and ecstasy. The study also found that alcohol and tobacco use had declined 13% and 29%, respectively. Conversely, the study also found that prescription drug abuse among young people had increased substantially during the same 5-year period. For example, past-year use of oxycodone, a prescription opioid, for nonmedical purposes had almost doubled since 2002. This trend has also been observed by several recent studies in both Canada and the United States, which report that the use of prescription opioids has become the predominant form of illicit opioid use. Although alcohol, tobacco, and marijuana remain the most commonly abused drugs, prescription drug abuse is quickly rising.

Gender Differences

Based on the results of the 2005 NSDUH, men reported being current drinkers more frequently than women. However, among the 12–17 age group, rates of current alcohol consumption were actually slightly higher for female youth in comparison to male youth (17.2% vs. 15.9%, respectively). This finding is consistent with the 2005 MTF study, which found that although males generally have relatively higher rates of heavy drinking than females, this pattern was reversed for 8th-grade and 10th-grade students.

In speaking specifically to alcohol use, women are more likely to be solitary drinkers and to drink in the home. It has also been consistently found that, on average, women tend to start drinking alcohol later in life, to drink alcohol less than men, and to have less adverse consequences related to alcohol use. However, in general, the same amount of alcohol or another drug taken by a man and a woman will have a stronger effect on the woman. The main reason for this is the biological tendency for women to have a higher percentage of body fat and a lower percentage of body water. Because women have proportionally more fat than water, there is less dilution of the drug while it is in the body of a woman. In addition, certain drugs bind selectively to fat cells in the body, which further contributes to their slower metabolism and elimination from the body of a woman.

Based on the 2005 NSDUH (as well as the 2005 MTF survey), males age 12 and older were more

likely to report current illegal drug use in comparison to females, particularly with respect to marijuana, whereas rates of using prescription-type drugs for nonmedical purposes were almost equal across gender. Among youth between the ages of 12 and 17, rates of illegal drug use were found to be very similar across gender, whereas the other two general trends still prevailed (i.e., male youth report more marijuana use, and abuse of prescription-type medications was approximately equal).

According to the National Institute for Drug Abuse (NIDA), although men are more likely than women to find themselves in situations where drugs are available, given the opportunity to use drugs for the first time, both are equally likely to do so. Men and women are also equally likely to have problems with cocaine, heroin, hallucinogens, tobacco, and inhalants. However, there appears to be gender differences in vulnerability to abusing specific substances. Women are more likely than men to have problems with sedatives, hypnotic drugs, and drugs designed to alleviate anxiety, whereas men are more likely to abuse marijuana and alcohol.

Theories of Substance Abuse

Although there is still widespread dispute about the cause of drug abuse, several models have gained prominence. The moral, disease, and biological models argue that the cause of drug abuse originates from within the individual, whereas social learning theory, systems theory, and the sociocultural model view the social environment as most influential. The biopsychosocial model combines elements from several of these theories into a single, integrated approach.

Individual Theories

The moral model argues that drug abuse is a choice, and that individuals are personally and morally responsible for the problems that may result from drug abuse. Alternatively, the disease model postulates that drug abuse is a progressive and irreversible disease with biological origins and perhaps also psychological and spiritual causes. This model is the foundation of many self-help groups such as Alcoholics Anonymous and Narcotics Anonymous. The biological model, which appears to be endorsed by the National Institute on Drug Abuse (NIDA), posits that drug abuse is largely a result of genetic and physiological processes. NIDA argues that although initial drug use may be voluntary, the ensuing abuse is often driven by neurological changes that affect behavior.

Social Theories

Social learning theory, first proposed by Albert Bandura, when applied to drug abuse presumes that drug abuse results from complex learning, including modeling and other forms of observational learning, and is grounded in the interaction of the individual with his or her environment. In contrast, systems theory places greater primacy on familial processes, such as dysfunctional interaction patterns within a family system, that can lead to drug abuse. The sociocultural model proposes that drug abuse is a logical consequence of the particular social norms and laws of many subcultures and societies.

Integrated Approaches

The biopsychosocial model integrates three major domains known to influence behavior: biological, psychological, and social factors. The biopsychosocial model posits that each of these factors contributes in some interactional way to drug abuse. Although this model is more complex than the other major theories, many argue that it more accurately reflects the complexity of human experience.

Another integrated approach developed by James Prochaska, John Norcross, and Carlo DiClemente is the transtheoretical model of change. It is an evidence-based model used to guide assessment, treatment, and policy, and is discussed in further detail in the diagnosis and assessment section.

Risk Factors for Drug Abuse

Although research has identified a number of risk factors for drug abuse, there is no single, reliable predictor of who will abuse drugs and who will not. With this caveat in mind, the Center for Substance Abuse and Prevention, a branch of the Department of Health and Human Services' SAMHSA, has organized risk factors for drug abuse into three groups: individual factors, family factors, and environmental factors. Individual risk factors include antisocial behavior (such as criminal activity and violence), social isolation, high need for independence, psychopathology, positive attitudes toward drug use, poor impulse control, and thrill-seeking

personality type. Family factors include parental drug use, poor family relationships, interpersonal conflict, and physical or sexual abuse. Environmental factors include peer influence, rejection or low acceptance, cultural or social norms, poverty, neighborhood disorganization, scholastic failure, low scholastic involvement, and negative school environment. Awareness of these risk factors can help in the early identification of individuals likely to begin abusing or continue abusing drugs.

Diagnosis and Assessment

Diagnosing drug abuse is essential for the provision of treatment services, yet the abuse of drugs is often difficult to assess. Many individuals who abuse drugs are not willing to disclose their habit, may be plagued by feelings of shame, or may fear legal retribution for their disclosure. Moreover, individuals who abuse drugs may deny the seriousness of their problem, both to themselves and to others. In light of these barriers to effective assessment, in the book *Where to Start and What to Ask: An Assessment Handbook*, Susan Lukas has suggested that questions such as the following may be useful in helping determine whether an individual needs a formal assessment for drug abuse: What substances does the individual use? How recently has he or she used them? How much does he or she use? When does he or she use? What happens when he or she uses? Why does he or she use? What effect is the substance having on his or her life? Does he or she feel guilty about his or her use? Has the individual ever tried to cut down or stop using? How did he or she try? Did it work?

After these types of questions have been answered, seeking a diagnosis may be useful in determining what type of treatment will be most beneficial. The most widely used and accepted method of diagnostic classification in Canada and the United States is the *Diagnostic and Statistical Manual of Mental Disorders*, (Fourth Edition, Text Revision) (*DSM-IV-TR*), published by the American Psychiatric Association. The use of *DSM-IV-TR* diagnostic terminology is useful because it offers standardized, descriptive criteria that can be used to ensure effective clinical communication about drug abuse.

According to the *DSM-IV-TR*, substance abuse is essentially characterized by clinically relevant impairment or distress as evidenced by at least one of the following symptoms for a 12-month time frame:

(a) repeated failure to fulfill major work, school, or home obligations; (b) frequent use in physically hazardous circumstances (including driving under the influence of substances); (c) persistent substance-related legal troubles; or (d) recurrent use despite ongoing or repetitive social or interpersonal problems caused by or worsened by substance use. Categories of drugs that qualify for a diagnosis of substance abuse, according to the *DSM-IV-TR*, are alcohol; amphetamines; cannabis; cocaine; hallucinogens; inhalants; opioids; phencyclidine; and the category of drugs comprising sedatives, hypnotics, or anxiolytics (anxiety-reducing drugs). Drugs that do not fit these categories can be classified as "other" (i.e., abuse of other substances). The *DSM-IV-TR* further distinguishes between substance abuse and substance dependence, the latter of which is characterized by at least 12 months of the continued presence of three or more of the following symptoms: (a) drug tolerance; (b) drug withdrawal; (c) loss of control over use (in terms of amount or duration); (d) sustained desire or repeated unsuccessful attempts to stop or cut down; (e) substance-related preoccupation (e.g., most of one's time is spent obtaining the substance, using the substance, or recovering from its effects); (f) reducing or eliminating important social, occupational, or recreational activities; and (g) continued use despite evidence that a physical or psychological problem is caused or aggravated by substance use. The diagnosis of substance dependence is further specified by the presence or lack of physiological dependence (i.e., evidence of tolerance or withdrawal symptoms).

The International Statistical Classification of Diseases and Related Health Problems, Version 10 (ICD-10) is a diagnostic system developed by the World Health Organization that is used in many countries outside of Canada and the United States. The ICD-10 defines harmful substance use (similar to the *DSM-IV-TR* diagnosis of substance abuse) as a pattern of psychoactive substance use that results in physical or psychological damage to one's health. Like the diagnosis of substance dependence in the *DSM-IV-TR*, the ICD-10 includes criteria for diagnosis of dependence syndrome to describe drug addiction. Dependence syndrome is defined as a cluster of behavioral, cognitive, and physiological phenomena that develop after repeated substance use and that typically include (a) a strong desire to take the drug, (b) difficulties in controlling usage, (c) persistent use despite harmful consequences, (d) a prioritizing of drug use over other

activities and commitments, (e) increased drug tolerance, and (f) possible physical withdrawal symptoms.

Many agencies in the United States and elsewhere have implemented Prochaska, Norcross, and DiClemente's transtheoretical model as a method of assessment and treatment. It is an integrated, evidence-based model that describes a stage-based pattern of change based on an individual's readiness to change. According to the transtheoretical model, determining what stage of change an individual is in is essential to providing appropriate and effective treatment. The individual who abuses drugs is assessed to determine what stage of change he or she is in, and treatment strategies geared to that particular stage of change are then implemented. The stages are as follows:

- *Precontemplation:* The individual does not recognize the need for change and does not have any intention of changing his or her pattern of drug abuse.
- *Contemplation:* The individual is seriously considering making a change. However, the individual does not have specific plans to stop abusing drugs in the near future.
- *Preparation:* The individual is planning to stop abusing drugs within the next month, but may still be ambivalent about taking action.
- *Action:* The individual has stopped abusing drugs but has done so for less than 6 months.
- *Maintenance:* The individual has stopped abusing drugs for more than 6 months.
- *Relapse:* The individual has returned to abusing drugs.

Treatment

Treatment Types and Settings

Although some individuals who abuse drugs resolve their problem spontaneously without help, formal treatment has been shown to be helpful for many individuals. There is evidence that those who receive some type of professional help subsequently reduce their use of substances and show improvement in other areas of functioning. In addition, psychological treatments targeting significant life problems also tend to improve substance abuse recovery outcomes. Reliable evidence has been demonstrated for the effectiveness of a number of treatment approaches, including social skills training, self-control training, brief motivational counseling, behavioral marital therapy, stress management training, and community reinforcement

approaches. Some evidence of positive effect has also been found for covert sensitization, behavioral contracting, the medication disulfiram (brand name: Antabuse), and antidepressants.

Treatment can be implemented in a variety of settings, which may include inpatient medical detoxification and stabilization in acute care facilities, dual-diagnosis hospital inpatient care, short- and long-term residential treatment, outpatient full-day treatment, temporary transitional residential treatment (halfway housing), and intensive or nonintensive outpatient programs.

Best Practices Guidelines

Both Health Canada and the NIDA have independently developed a series of research-driven best practices guidelines for drug abuse treatment and rehabilitation. Some highlights of these best practices include the following:

- Pharmacotherapies such as methadone and disulfiram can be effective as supplemental treatments when used in a controlled setting.
- Behavioral therapies such as relapse prevention programs, behavioral self-control therapy, and behavioral contracting have been shown to be useful when administered either individually or in group settings.
- In terms of alcohol abuse, a community reinforcement approach has been shown to be effective for those with few social resources and relatively severe use.
- Marital therapy and social skills training are both well supported by research.
- Stress management interventions have been shown to be useful as part of alcohol treatment programs.
- Services should be flexible and individualized, and guidelines for the selection of appropriate services are essential. No single treatment is appropriate for all individuals, and treatment needs will likely change as treatment progresses.
- Group therapy is often preferable to individual treatment, unless otherwise contraindicated.
- Although research generally supports the relative cost-effectiveness of outpatient treatment, some individuals may benefit from both residential and outpatient or day programs.
- Effective treatment combines interventions that address the multiple needs of the individual, not just his or her drug use.
- Brief interventions of up to eight sessions have been shown to be especially effective for socially stable individuals with low to moderate alcohol dependence,

and are usually as effective as treatments of a longer duration for this group of individuals.

- Counseling provided by competent therapists with strong interpersonal skills is related to positive outcomes.
- The majority of those who have drug abuse problems do not seek help; therefore, more effort is required to increase awareness of specialized services to the general public as well as to health service providers.

It is expected that widespread application of these guidelines in drug abuse treatment will contribute to increased positive outcomes for substance-abusing individuals seeking support.

Prevention

Many people believe efforts at preventing drug abuse are vastly underfunded in comparison to the funds put toward treatment. Prevention in the context of drug abuse refers to the avoidance or mitigation of drug abuse and problems associated with drug use. Drug abuse prevention can involve primary, secondary, or tertiary prevention. The goal of primary prevention is to prevent drug use or abuse from occurring in the first place. Early education campaigns that encourage children to "just say no" would be an example of a primary prevention strategy. Secondary prevention involves interventions applied to those who are already in the early stages of using or abusing drugs in order to prevent the development of additional problems. An example of secondary prevention would be mandated alcohol education classes for those convicted of driving under the influence. Tertiary prevention involves reducing or stopping further deterioration among those with an established history of drug abuse. Harm reduction strategies designed to reduce harmful effects for those who continue to abuse drugs are seen as tertiary prevention strategies. An example of a harm reduction strategy is safe injection sites, such as those in Vancouver, British Columbia, Canada, that permit individuals to inject self-obtained illegal drugs in a setting staffed by medical professionals in an effort to prevent overdoses and the spread of communicable diseases.

Three major models of drug abuse prevention have emerged over the years, each with its own underlying philosophy and subsequent suggestions for prevention policies. The sociocultural model argues that social norms are the key factor in promoting the abuse of drugs. An example of the sociocultural model of prevention is social-norm education (as provided by many college health centers and college counseling centers), which seeks to counter common misperceptions about typical levels and patterns of drug usage. The consumption model argues that the prevalence of drug abuse is a direct function of the average levels of consumption in a given culture (e.g., the more the individuals in a culture drink, the more individuals in that culture who will abuse alcohol) and seeks to minimize the negative consequences of drug use through the implementation of restrictions. Higher taxes and age minimums for legal alcohol consumption would fall within the consumption model of prevention. The proscriptive model goes one step further and argues that if the availability of drugs (particularly alcohol) is completely prohibited, those who continue to abuse drugs can be regarded as bad or immoral. Therefore, the proscriptive model of prevention advocates for prohibition of availability and complete abstinence. The American Alcohol Prohibition Era (1921 to 1932) is an example of the proscriptive model at work.

In the past, several mass media campaigns have been aimed at youth and young adults in an effort to reduce drug abuse. Although these campaigns have been shown to increase public awareness and knowledge about drugs, their effectiveness at actually reducing drug use and abuse has not been consistently demonstrated. A recent prevention strategy that has shown promise is resistance skills training, which helps youth develop their problem-solving and decision-making skills. It also seeks to help youth develop cognitive skills for resisting media-based drug use messages, increase self-awareness and self-esteem, learn nondrug coping strategies, and develop interpersonal communication and assertiveness skills. The most widely used program of this kind in the United States is the Drug Abuse Resistance Education (DARE) program. Unfortunately, research on its effectiveness has yielded mixed results.

DYNAMICAL SYSTEMS

Educational psychology focuses on theories of learning that ultimately affect how students are taught. Behavioral learning theories influenced the teaching/ learning process for more than 50 years. In the 1960s, the information-processing approach brought the mind back into the learning process. The current emphasis on constructivism integrates the views of Jean Piaget, Lev Vygotsky, and cognitive psychology. Additionally, recent scientific advances have allowed researchers to shift attention to biological processes in cognition. The problem is that these theories do not provide an integrated approach to understanding principles responsible for differences among students in cognitive development and learning ability. Dynamic systems theory offers a unifying theoretical framework to explain the wider context in which learning takes place and the processes involved in individual learning.

Dynamic (or dynamical) systems theory is part of a paradigm shift involving the acceptance of chaos and complexity as theoretical frameworks in physics, biology, chemistry, engineering, ecology, and psychology. Its concepts can be applied to any systems that change over time. It emphasizes the complexity of learning and the students themselves. It recognizes the importance of context in change. It connects the physical with the mental. It allows teaching and learning to be connected processes.

Dynamical Systems Are Self-Organizing

Dynamic implies synergistic, changing, and chaotic (i.e., underlying order that appears random). *System* denotes an assemblage of interacting components whose essential properties arise from the relationships between its parts. Students, teachers, classrooms, schools, and school districts make up dynamical systems in education.

Students and teachers are individuals made up of diverse systems—biological, affective, and cognitive. There is also diversity based on race, ethnicity, gender, disability, and socioeconomic status—other systems that are an integral part of students and teachers. All of these systems contribute to individual differences in rate of learning, level of thinking, memory, and motivation. Pedagogically, teachers need to be aware of the dynamic complexity of their students and themselves

in order to more effectively understand what occurs in the teaching-learning process. For example, an African American student who has lived in a rural town will perceive information differently from an African American student who has been raised in an inner-city ghetto. Even though both students are African American, the differences in the systems that make up who they are will contribute to diverse outcomes. If both are learning the word *field*, their understanding of the meaning of this word will reflect their different experiences. The same teaching strategy may not work for both of them. For one, a trip to a field might be necessary whereas the other will have experience with fields and can easily make a connection. A view of students as dynamic systems emphasizes the individuality and complexity of all students.

Each dynamic system, in addition to being fluid and integrative, exists in a *state space*, which is an abstract construct depicting the range of behavior open to a system and constrained by the degrees of freedom available to the elemental components of the system. Each student has his or her own state space or possible behaviors. For example, a student whose family speaks Spanish at home is going to be constrained by English being a second language. His or her state space will be different from that of a student for whom English is a primary language. In order to be effective, a teacher needs to be sensitive to the different state spaces of his or her students. Some students may be incapable of carrying out certain behaviors because of the limits of their state space. The student with Spanish as the primary language may be incapable of understanding certain English idioms until he or she has learned other words first and changed his or her state space through self-organization.

Where a system is located in state space is often determined through *self-organization*, which occurs when a system is attracted to a preferred state of being out of many potential states. The individual components of a system emerge into new patterns (states of being) without anyone or anything directing this change. Self-organization emerges from the confluence of components within the system. In order for self-organization to occur, the system must be complex and open to changes in the environment.

Self-organizing, nonlinear dynamic systems tend to migrate toward certain conditions or behaviors that are called *attractors*. Attractors have varying degrees of stability. Some are easily changed, such as the heart rate when exercising. Others are not easily changed,

such as the stomach producing acid in response to food. An attractor state for a student might be his or her reading level, which may be stable for a long period of time.

Systems will remain in a certain state space until a perturbation pushes the system or increases the system's attraction to another state. *Perturbation* is a disturbance to the system. When disturbed, a system may move away from its present attractor and toward a new attractor, resulting in a *phase shift*. A phase shift is a new form that emerges from the loss of stability of the existing forms. For example, the student whose reading level has been stable for a time period might change to a higher level because of an interest in a more difficult book. The resulting phase shift might be observed as the student begins reading chapter books instead of picture books. There has been a phase shift in reading levels.

From a dynamic systems approach, learning is a self-organizational process on the part of the individual. The student undergoes phase shifts (transitions) in which the cognitive system self-organizes and new patterns of understanding emerge. Students pass from one organized state of the system to another. Along with the cognitive system undergoing change, neuronal networks are strengthened. As these systems change, they affect the other systems that make up the individual student.

Phase shifts can also be facilitated by a *control parameter*. A control parameter is a variable outside the system to which the system is sensitive and that moves the system through different states. Teachers use control parameters to perturb the attractor states of the students. In pedagogy, a control parameter is the teaching method. Some teaching methods are more successful than others. If successful, self-organization (learning) occurs. If there is no immediate self-organization, then the control parameter perturbation may disturb the system so that at some later point in time, self-organization may occur.

For example, if a teacher is focusing on addition in an elementary classroom, he or she will use methods to bring about an understanding of addition. When a student understands what addition is, he or she undergoes a transition. Not only has his or her cognitive system changed, but biologically, there are changes in the brain; emotionally, the student might feel satisfaction and pride about mastering something in school; and environmentally, the student might be able to use addition in new aspects of his or her life, such as shopping with parents. The student, as

a dynamic system, has self-organized and is no longer the individual he or she was prior to the new learning.

One truth about learning is that it evolves over time. Therefore, learning does not occur in every student each time a topic is covered in class. What often occurs is a perturbation of the attractor state. There can be many small perturbations without a change in the cognitive system. It is when the system (student) self-organizes that learning takes place. For example, a teacher may introduce addition to students in a number of different ways—direct instruction, small group activities, individual worksheets. The actual comprehension of what addition means will occur in individual ways. Some students may understand addition from the first activity, and therefore will self-organize, move to a new attractor state in which being able to add is the norm, and be able to demonstrate an understanding of addition. Other students may require all three strategies before meaning is created. Each activity perturbs the attractor state of these students, but no self-organization occurs until all activities have been experienced.

Dynamical Systems Are Nonlinear

Besides self-organizing, dynamic systems are also *nonlinear*, that is, output is not proportional to input. Teachers learn early that sometimes the best lesson plans do not bring about the learning that was sought. Pedagogically, there is not always a direct relationship between teaching and learning. Sometimes, a teacher does not have direct control over the specific learning that goes on, such as in a cooperative learning group, where students can learn from other students without the teacher's involvement. Most of the time, the teacher has to use a number of strategies to perturb the systems (students) until finally self-organization (learning) occurs.

All Systems Have a History

Dynamic systems theory espouses that all systems have a history that affects their states in the present. As the student acts, that action becomes part of his or her dynamical history. This history will then influence future actions. Fritjof Capra states that living structure is always a record of previous development. The history of a system includes its tendencies and constraints. Self-organization taking place in the present is constrained by self-organization of the past. The system's history will affect its present state space, attractors, phase shifts, and control parameters.

So, besides viewing students as dynamical systems, teachers must be aware that each of these systems (students) has a history that will affect his or her ability to learn. Some students have a history of doing well in school, understanding academic subjects, and having friends and supportive parents. Unless severely perturbed, these students will continue to do well in school throughout their school lives and respond well to teaching strategies. Other students do not have such a positive experience in their pasts. They may have problems being in school, may have difficulties learning academic subjects, and do not have supportive parents. These students may be harder to reach and require larger perturbations to their systems before learning can occur. Their histories may interfere with success in school. These are often the students who present the challenge to teachers.

Besides the students and teacher being systems with a history, the classroom community, too, is a system that has an ongoing, ever-changing history—a history of interactions within the enclosed walls of the classroom itself. No two days are alike in the classroom; indeed, no two moments in time are alike. The setup of the classroom—temperature, luminosity, desk orientation, ambient noise, odors—defines its state space. Within that broader framework, each member of the classroom community, each student and teacher, is an independent, complex, nonlinear system with a unique state space of his or her own and his or her own unique and constantly changing history. The variability and unpredictability of the classroom environmental system keep it in constant flux.

The environment also constrains the degrees of freedom available to individual students and teachers. For example, students learn to raise their hands to speak, speak softly or not at all while working, and get into line in the proper order. All of these constrain the behaviors of the students from what they might be if students did not have certain norms. Some students learn from this history of classroom behavior and automatically apply it in subsequent grades so that by the time the students reach later elementary years, the attractor state for classroom behavior is stabilized.

Understanding Dynamical Systems Within the Context of the Whole

Because a number of systems make up an individual, all of them, together, provide the essence of the

individual. Unlike the behaviorist reductionist view, which requires studying parts of the whole and then generalizing across the whole, dynamic systems theory purports that the whole is always different from the mere sum of its parts. Therefore, the parts must be studied and understood within the context of the larger whole. This holistic thinking moves the focus of research from objects to relationships. Studying learning in a classroom setting did not begin until the 1960s, yet this is where the majority of children's academic studies take place. Students are taught within groups of students, yet learning is a very individual activity.

It is important for the teacher to know the history of each student in order to understand what attractors are present and what control parameters might facilitate change. However, this is difficult to do because teachers are involved with groups of students in such a way that time and energy prohibit study of the various systems that make the student who he or she is. So instead, teachers use a variety of learning techniques in order to bring about learning in the most students possible.

Besides the students being made up of different systems, the teacher also is a network of systems with his or her attractor states and state space. This will affect what types of pedagogical practices he or she will use in a classroom setting. For some teachers, teacher-centered strategies are what they are comfortable using, and despite information to the contrary, they will continue in that attractor state because of its stability.

DYSLEXIA

Dyslexia is one of several types of learning disabilities that occurs in children who, despite strengths in other academic and cognitive abilities, experience extreme difficulty in learning to decode and spell printed words. This problem at the level of the single word impedes their ability to fluently read and comprehend connected text. Importantly, their reading difficulties do not stem from lack of educational opportunity, sensory acuity deficits, or socioeconomic disadvantage, although educational opportunity and socioeconomic status may interact with dyslexia to either reduce or exacerbate its severity. The International Dyslexia Association defines dyslexia as follows:

> A specific learning disability that is neurological in origin. It is characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede the growth of vocabulary and background knowledge.

Estimates suggest that dyslexia occurs in 6% to 17% of the school-age population depending on how it is defined. Regardless of prevalence estimates, children with dyslexia comprise the bulk of children receiving special education services in the United States for students with learning disabilities. Although

dyslexia manifests in childhood with the onset of formal reading instruction, it has definable precursors that permit early detection before formal schooling. In the absence of targeted intervention, the deficiencies observed in childhood continue to be evident in the same individuals well into adulthood. Dyslexia may also occur concomitantly with other conditions, including other learning disabilities involving mathematics (dyscalculia) and written expression (dysgraphia), oral language disorders, and attention deficit disorder with or without hyperactivity. These co-occurrences are usually comorbid, meaning that the child has more than one problem.

Scientific understanding of dyslexia has dramatically increased in the past four decades. It is now widely accepted that dyslexia occurs on a continuum in much the same way as obesity or high blood pressure. What this means in practice is that dyslexia is not an all-or-nothing categorical disability. Instead, it occurs in degrees of severity. Establishing the cut point on the continuum at which word reading difficulties constitute a disability is not well established and accounts for the variability in prevalence estimates. Current classification schemes vary by state and by program type. In the United States, children can receive services for dyslexia as part of special education under the Learning Disabilities (LD) category in the Individuals with Disabilities in Education Act (IDEA), where problems with basic reading skills are one of the eight domains in which LD can occur. A few states, such as Texas and Louisiana, also provide dyslexia services outside of special education. In most states, qualification for dyslexia services under the LD category would be based on an achievement/IQ test discrepancy, with a number of discrepancy models in use from state to state. In the recent reauthorization of IDEA, states were also allowed to use response-to-intervention (RTI) as a mechanism for identifying learning disabilities including dyslexia as well as models based on discrepancies in achievement relative to age. Regulations permitting the use of RTI for identification are just emerging from different states.

Historical Roots and Theories

Over the years, a number of other theories and resulting treatments have gained and lost prominence in the field of dyslexia. A few of the most prominent theories are briefly reviewed below.

Deficits in Visual Perception

Dyslexia was first described more than 100 years ago. By 1900, the condition was referred to as *congenital word blindness* and was believed to be caused by difficulty in storing visual impressions of words. Building on the assumption that the underlying causes of observed reading difficulties were based in deficits in visual processing, Samuel Orton outlined the first fully developed theory of dyslexia, which he called *strephosymbolia* (twisted symbols). His theory suggested that children were experiencing difficulty in establishing hemispheric dominance within the brain, resulting in an inability to suppress mirror image counterparts, which was presumed to cause optic reversibility in visual perception that resulted in seeing symbols as reversed images (e.g., *b* as *d*; or *was* as *saw*).

Although the basic tenets of Orton's theory have not proved to be correct, they have been hugely influential in driving the focus of subsequent theories and treatments of dyslexia even to the present time. It is from Orton's theory of dyslexia that the widely held belief that the treatment of dyslexia requires multisensory methods of instruction stems. The underlying assumption being that by activating the auditory, tactile, and kinesthetic modalities of learning, students are able to compensate for inherent weakness in the visual domain. In fact, the Orton–Gillingham method for teaching reading, or one of many derivatives of this method, is pervasive in the treatment of dyslexia even today. However, empirical support for these methods is mixed. Likewise, there is no indication that the multisensory aspects of this instruction are actually the salient aspects of the instruction. The content of these programs focuses on teaching alphabetic decoding, and this focus likely accounts for any effects achieved. Interventions that do not actually include multisensory aspects but do carefully teach alphabetic decoding have also achieved very positive results with this population.

The view that dyslexia was caused by dysfunction in the visual perception system dominated the field until it was systematically evaluated in the 1970s and 1980s. Outcomes from these studies clearly demonstrated that the visual perception ability of dyslexic and normal readers was not different, and that visual perception ability does not predict performance of reading ability.

Low-Level Visual Deficits

Dyslexia has also been attributed to visual tracking problems assumed to be caused by ocular motor

deficiencies; visual masking effects associated with deficits in the transient visual system; and scotopic sensitivity syndrome (SSS) involving excess sensitivity of the retina to particular frequencies of light, causing the brain to distort information. Of these theories, SSS currently has the most prominence in practice. The interventions recommended for SSS involve placing colored overlays over text or using tinted lenses designed to selectively filter out problem frequencies and make the text visually stable.

The visual tracking theory of dyslexia has long been discredited by well-controlled eye movement studies finding no differences between poor and normal readers. Similarly, the evidence to support the theory of visual masking effects has been weakened by the finding that significant numbers of normal readers have similar transient system deficits. Likewise, independent reviews of the results of interventions based on SSS theory have not found specific associations of reading, dyslexia, and other disabilities.

Perceptual-Motor and Cerebellar Deficits

In the 1960s and 1970s, theories commonly attributed the cause of dyslexia to perceptual-motor deficits. Although the specifics of each theory differed, they shared the common belief that a child must have adequate visual-motor functioning as a prerequisite for academic learning, and that motorical treatment was needed to reorganize neurological functioning to allow adequate visual-perceptual ability. The treatments aligned with these theories included such things as having children practice creeping and crawling, walking on balance beams, standing on balance boards, and completing eye-tracking exercises. Although these theories and their accompanying treatments were very popular, they did little to improve the academic outcomes for children and have largely become extinct in practice.

Despite these results, there has recently been some resurgence of this approach to treating dyslexia and other learning disabilities, despite the lack of scientific evidence for effectiveness. This is most apparent in the cerebellar theory of dyslexia proposed by Roderick Nicolson, Angela Fawcett, and Paul Dean. The hypothesis is that children with dyslexia fail to automatize reading and other cognitive and motor skills mediated by the cerebellum. There is little evidence that supports this hypothesis or the recommended interventions.

Low-Level Auditory Deficits

Another theory that has attracted attention more recently is put forth by Paula Tallal, who theorized that children with dyslexia are fundamentally impaired in processing acoustic stimuli characterized by spectral parameters that change rapidly in intensity. Although originally based on children with oral language disorders, Tallal expanded this hypothesis to children with dyslexia, suggesting that dyslexia is caused by lower-level auditory problems interfering with the processing of sounds with rapidly changing properties, which in turn impairs speech perception and thus the acquisition of phonological awareness and phonological decoding. Early empirical evidence provided support for this theory, but more recent investigations have not found specific associations of these perceptual problems with dyslexia. The treatments that have emerged from this theory, which involve using synthetic speech to slow down the acoustic stimuli, have not been found to have a major impact on reading skills in randomized, controlled experiments.

Phonological Coding Deficits

Currently, the theory that dyslexia is the result of weak phonological coding has accumulated substantial and converging scientific evidence to support it. Phonological coding is the ability to use speech codes to represent words and parts of words. Weakness in this domain results in poor phonemic awareness and letter-to-sound mapping, resulting in poorly specified phonological representation of words. These coding deficits result in difficulty in storing and retrieving words as unitized orthographic representations, and difficulty in processing alphabetic information in working memory. The theory suggests that difficulties in storage and retrieval impair the child's ability to form necessary connective bonds between spoken and written words, which in turn impedes the storage of fully specified representations of word spellings and thus impedes fluency of word recognition.

Evidence to support this theory comes from two sources. First, a relation between phonological coding and dyslexia can be inferred because children with dyslexia have consistently been found to perform significantly below normal readers on different assessments of phonological processing, Likewise, a causal link can be inferred because intervention studies directly addressing phonological coding deficits have

repeatedly demonstrated positive outcomes on the reading outcomes of children with dyslexia. There is controversy over the exact manifestations and contributions of different phonological processing domains, but the link of word reading and phonological processing, and the extrapolation to dyslexia, is widely recognized as a major scientific discovery.

Neurobiological Correlates

Dyslexia has always been assumed to be neurobiologically based. However, only recently have the neurological and biological causes of dyslexia been able to be examined directly rather than just inferred.

Genetics

Studies of the heritability of dyslexia show that there is a strong genetic link for reading and reading disability. For example, a child whose parents had reading problems is eight times more likely to experience a reading problem; 25% to 60% of parents of children who are dyslexic also experienced significant reading difficulties; and the rate of concurrent dyslexia among identical twins is above 80%, but below 50% for fraternal twins. The estimates of the genetic contribution ranges from 50% to 80% depending on age, schooling, and other sample characteristics. Furthermore, recent studies have identified a constellation of specific genes involved in dyslexia. Multiple researchers have identified an area on chromosome 6, and chromosome 15 has been identified by several researchers. Potential markers on chromosome 1 and 2 have also been reported but not replicated.

Even though there is a clear genetic link to dyslexia, these studies do not indicate that the genetic links are specific to dyslexia, but instead are linked to reading and the variability in reading skills that characterizes any population. In addition, the same body of research demonstrates that the environment plays an important role in determining reading outcomes for individual children. Whether or not significant reading problems will develop in a child with a genetic predisposition for dyslexia also depends on what types of reading experiences that child is provided in his or her home and school environment. Even if heritability is strong, the genetic contribution does not mean that the reading problem is immutable to intervention, although more intense and targeted instruction may be needed.

Brain Function

The evidence that dyslexia is greatly influenced by environmental factors is supported in recent neuroimaging studies of brain function in students with and without dyslexia. In these studies, various neuroimaging techniques, such as positron emission tomography, functional magnetic resonance imaging, and magnetic source imaging, are used to assess the brain's response to cognitive challenges. The findings from studies using these techniques converge to show that tasks requiring reading are associated with increased activation with the basal surface of the temporal lobe, the posterior position of the superior, the middle temporal gyri, and the inferior frontal lobe. Magnetic source imaging studies, which allow time sequences within the brain to also be mapped, demonstrate that in normal readers, the occipital areas of the brain that support primary visual processing are activated first, followed by regions in the basal temporal areas in both right and left hemispheres. This is followed by simultaneous activation in three areas of the temporal and parietal areas corresponding to the superior temporal gyrus, Wernicke's area, and the angular gyrus, often more predominantly in the left hemisphere. Students with dyslexia activate the same regions of the brain, but there is often much less left hemisphere activation and differences in the temporal sequences of brain activation.

More recently, a series of studies has been conducted to determine the impact of carefully designed instruction on phonological coding on the brain activation patterns of children with or at risk for dyslexia. In each of these studies, the brain activation patterns of children at risk for dyslexia (i.e., 5- and 6-year-olds) or identified as dyslexic (i.e., 7- to 17-year-olds) show predominantly normalizing patterns after well-designed, intense interventions. Importantly, this finding has been found among both young readers prior to the onset of reading difficulties (i.e., intervention in first grade) and older children and adults who have experienced serious reading difficulties. These studies indicate that the neural systems that mediate word recognition and dyslexia are malleable and responsive to intervention.

Effective Treatment

Since the early 1990s, a number of studies have carefully evaluated interventions designed to prevent or

remediate dyslexia. From this body of research, we now know much about what constitutes effective intervention for these children. Perhaps the most important finding is that the needs of children with dyslexia are not unique to only children with dyslexia. The same type of instruction that is effective with these children is also highly effective for other children who experience reading difficulties for other reasons, such as economic disadvantage. Likewise, the critical components of this instruction are the same for even normally developing children, although the level of intensity and amount of repetition needed will be greater for children with dyslexia.

This critical content includes explicit and strategic instruction to ensure that children develop high levels of phonemic awareness; in-depth knowledge of letter-sound correspondence, including the many spelling variations; acquisition of accurate, quick, and flexible word recognition skills moving beyond the single syllable; smooth, fluent oral reading through adequate practice reading increasingly more complex text; and strategies for the deep processing of text. For the treatment of dyslexia, the most crucial component of instruction is the inclusion of explicit instruction in fluent word recognition that includes phonological recoding (i.e., sounding out words) as a word recognition strategy. Phonological recoding appears to account for individual differences in word recognition in both children and adults and is at the heart of phonological coding problems. When instruction is sufficiently intensive and integrates these various components into daily instruction that cumulatively becomes increasingly more complex, children with dyslexia improve considerably in not only accuracy of their word recognition skills, but in their overall reading ability. Particularly striking results are apparent among young children who have not yet experienced reading difficulties, but who have risk characteristics of dyslexia. In multiple studies, the occurrence of reading problems among students at risk for dyslexia and other reading problems has been reduced to below 1.5% of the total population.

One of the most exciting developments in reading research is dramatic growth in researchers' understanding of which skills predict a phonological processing core deficit. Today, researchers can confidently predict which children are most at risk for developing dyslexia and other reading problems as young as kindergarten age. Thus, it is now possible to identify risk for dyslexia early, provide high-quality intervention before failure has occurred, and in most cases normalize reading ability. Early literacy skills that have been demonstrated to accurately predict risk in young children include (a) phonemic awareness; (b) knowledge of letter names and sounds; and (c) speed of lexical retrieval measured through the rapid naming of objects, colors, digits, or letters.

For children who are not identified early, the outlook is not as positive, with reading problems becoming more difficult to remediate by the end of third grade. Older children require more intense interventions, occurring for longer periods of time, than do younger children. Although the impact of early preventive and later remedial approaches are comparable, older children are usually so far behind that it is difficult to provide the intensity and reading experience that will make them completely proficient readers. Although the outcomes for these groups of children can be very impressive, major concerns remain about the development of fluent reading ability among older students even after intervention, partly because of lack of reading experience. Likewise, these children often have persistent deficits in vocabulary and comprehension that also may reflect an earlier inability to access print, as well as co-occurring problems with oral language development that affect listening and reading comprehension independently of phonological processing.

Instructional Programming

Programming to prevent or treat dyslexia and other reading difficulties has proven a great challenge within the public schools. Current proposals recommend a multitiered model of reading intervention. In most of the proposed multitiered models, Tier 1 is improved classroom-level general education core reading instruction so that critical content is taught well from the beginning. Children who experience difficulty in spite of receiving quality classroom-level instruction move into more intense, small group intervention (Tier 2) provided in addition to their core (Tier 1) instruction. The focus is not on labeling children, but rather on providing services to children at risk for reading failure for any reason. Only after a child fails to respond adequately to the first two levels of instruction would a child be considered dyslexic, requiring Tier 3, or ongoing, support. Tier 3 intervention is typically described as having greater intensity and duration than Tier 2 intervention. Different models

vary in the point at which special education eligibility and services would be provided.

Understanding Dyslexia

In the past few decades, much progress has been made in understanding both the causes and treatment of dyslexia. It is now understood that dyslexia is a neurobiologically based disorder of phonological core processing ability that causes individuals to experience severe difficulty in reading and spelling at the level of the single word. Furthermore, it is now known that although genetics plays a large role in determining if a child has a predisposition for developing dyslexia, the environment also plays a large role in determining the level of dyslexia expressed in any one individual. Environments that provide repeated and careful opportunities to practice phonological coding will result in a decreased expression of dyslexia. Furthermore, dyslexia is treatable, even among older children, although outcomes are generally better for younger children. However, this is simply because younger children have not yet fallen behind and thus don't have as much ground to cover in order to catch up.

A master can tell you what he expects of you. A teacher, though, awakens your own expectations.

—Patricia Neal

Early Child Care and Education

Early child care and education is defined as any care on a regular basis by someone other than a child's immediate family members. Infant and toddler care refers to this type of care for children from birth to age 3 years. Early care and education are important to educational psychology because they are associated with later cognitive and socioemotional outcomes for children in educational settings. In addition, with the historical changes that resulted in parents working outside of the home, increases in wraparound child care to include hours before and/or after the school day have become normative for school-age children, with implications for educational psychology. This review first defines the topic of early child care and education and outlines the different settings in which care takes place. This is followed by an explanation of the importance of early care and education environments to child development outcomes. Finally, the effect of family contexts in early care and education as they relate to child development outcomes is presented.

Types of Early Child Care and Education

Three main types of early care and education exist for infant and toddler groups. These are in-home care, services in child care homes, and services in child care centers. *In-home care* refers to care when an individual comes into the family's home to provide care. *Child care homes* and *centers* are out-of-home services where children receive care in another individual's home or at a location other than someone's home, such as a child care facility.

Importance of Early Child Care and Education Environments

The impact of physical environments and subsequent early experiences on early brain development makes consideration of early care and education environments important. Given the primary importance of the family to early child development, child care has been found to make a unique contribution in the area of cognition. This unique contribution is moderated by three known variables: the amount of time children spend in care, the quality of care, and the type of care. Specifically, the incidence of problem behavior and minor illness is higher in children who spend more than 30 hours per week in care. Regarding quality, infants and toddlers involved in high-quality child care have been shown to have better social cognition and better reading and math skills compared with children in low-quality settings. Last, regarding type of care, center-based care, compared with other types of care, is associated with better language, social skills, and pre-academic skills with respect to letters and numbers.

Models

Two important models of early child care and education exist that encompass both regulatory and process benchmarks for early care and education. The first is the Early Head Start program, administered by the U.S. Department of Health and Human Services, Administration for Children and Families, which is aimed at providing services to families with infants or toddlers living below the federal poverty level. The second is the military model of child care, instituted by the U.S. Department of Defense, aimed at providing early care and education services to military families.

These models share the philosophy that incorporating both child- and family-centered practices is integral to positive child outcomes. It is clear that the incorporation of both child- and family-centered practices is important from evaluation of the effects of child care in the lives of infants and toddlers from these populations. Specifically, it is clear from evaluation of the Early Head Start model, in particular, that over time children do better when parents have higher levels of education and income, when mothers have fewer symptoms of depression, and when families incorporate learning activities into their home, such as books and play materials, and are involved in their young children's play activities.

The Early Head Start Program Model

The Early Head Start program model is built on a framework encompassing four cornerstones to ensure best practices in delivering services to infants and toddlers and their families. These cornerstones include child development, family development, community building, and staff development. Within the cornerstone of child development, which includes child care services, program design incorporates many objectives related to quality child care. Specifically incorporated are the objectives of positive child health and development, education and early childhood development, child health and safety, good nutrition, and good child mental health. Within the objective to promote positive child health and development is the identification of activities that will foster children's physical, cognitive, and socioemotional growth in a child care setting. Because of the infant/toddler age of the children enrolled in these programs, emotionally secure parent–child as well as child care provider–child

relationships are seen as an integral component of fostering these areas of development. Thus, in addition to developmentally appropriate early care and education services, parental supports are in place to build strong parent–infant emotional connections. Supports include activities such as center- or home-based parent education as well as parental involvement in the child care program.

Community building is a component of the Early Head Start framework that stems from ecological theory, which recognizes the important interaction between the individual and larger systems. For families with infants or toddlers and limited resources, the Early Head Start programs have aimed to increase access to resources in the community. The comprehensive nature of the program has been shown to be important to families with limited resources who have infants or toddlers.

Staff development is a last important cornerstone to the Early Head Start programs that is universally important to child care. Teachers with more advanced training and education are also more likely to understand and use developmentally appropriate practices in the classroom. In fact, it has been established that developmentally appropriate behaviors in child care staff will increase directly as the number of hours of training received increases. Training, supervision, and mentoring in understanding and developing child socioemotional development are integral activities implemented in the Early Head Start program model to achieve the goal of staff development for the larger purpose of enhancing positive child outcomes.

The Military Model of Child Care

The U.S. military has developed a model of child care that exemplifies the way intensive reform can drastically improve a service such as child care. Before the Military Child Care Act of 1989, the military model of child care was very similar to, and plagued by, the same struggles as current civilian child care. The military model of child care came about as a result of a demographic shift in military personnel in the 1980s, as more men and women with families chose the military as a career. The low-quality child care arrangements available to military families before 1989, such as unsafe conditions, poor and unenforced standards, and extremely high staff turnover rates, hampered military readiness. For the military, such issues implied the need for an

improved child care system. This need was addressed and accomplished by creating a systematic approach to improving its child care system.

Today, the U.S. military has set in place a coordinated system for all of its branches. The key components of the system aim to improve quality through enforced standards, accredited programs, well-trained and well-compensated staff, and an increase in family-identified goals, such as affordability. The military model of child care systematically addresses universal needs for child care.

The military model of child care has improved its program quality by creating firm standards in all areas of care, including health, safety, staff–child ratios, and staff training. These standards exceed some state standards. Certification is done annually, and regulations are enforced through quarterly, unannounced inspections of child care programs. Meaningful sanctions are in place for when programs are found to be noncompliant with standards. Inspectors are given the latitude to deem a program necessary to be fixed, waived, or closed, reinforcing the intolerance for unsafe programs to remain open. The civilian child care community would benefit greatly from strict enforcement of quality standards as exemplified in the military model.

The military model incorporates a single point of entry approach to child care. This addresses the differing needs and wants of families as it pertains to care for their child(ren). Child care centers, family child care homes, and individual providers are maintained in one, current database that makes it easier for families to choose what is best for their family. This single point of entry method has two additional, positive consequences. First, it is easier for accreditation and monitoring to take place within a universal system. Second, resource and referral services are important to families choosing child care, and a universal system can be cost-effective to this important first step to finding child care for families. In civilian child care, some states have incorporated resource and referral services, yet many families are not aware of this service. Public information campaigns address this issue. Additionally, a statewide resource and referral system that links program accreditation and monitoring is a cost-effective way to address many issues simultaneously, such as family need for child care availability information and tracking of program accreditation and monitoring.

The National Association for the Education of Young Children (NAEYC) is an agency that rewards child care programs for going beyond mandatory licensing requirements through an accreditation system. In the military system, NAEYC provides financial assistance to child care programs. This accreditation standard in the military system has led 99% of centers to be accredited.

Moreover, half of children in military child care are under 3 years old. As a result of the large number of infants and toddlers in child care, improvement for this vulnerable population has been a priority in military reform. Within this system, children are able to enter at 6 weeks old and for up to 12 hours per day, as this is what is needed for many military families. An additional need, for many military families, is child care services provided during "off" hours, such as during evenings or on weekends. As the economic environment changes, civilian families face circumstances similar to those of military families; for example, extended family may not be in the same vicinity. Thus, the need to rely on professional support for child care is a reality for both military and civilian families. The military model of child care has focused reform on providing flexible care schedules to families.

To address the needs of infants and toddlers, military child care policy has also instituted primary caregiver assignments of one child care provider to a child. Additionally, infants are allowed individual sleeping and feeding schedules and sleep in cribs with the rest of the group, rather than in a separate sleeping room. Policy has also emphasized safety and sanitation for this age group. Child care centers have incorporated building design that decreases the spread of germs and reduces child accident rates through exitways from infant and toddler classrooms to outdoor play areas designated specifically for different age groups.

The military model of child care incorporates policies above and beyond state licensing requirements. Policies such as standard use of surveillance cameras in the classrooms and a diaper-changing rotation among staff (so that no one individual is responsible for diapering) can decrease the incidence of child abuse.

Last, within the military model, parents are seen as constituents and are, thus, involved in programs—for example, through their presence in the centers and through their decision-making capacity. Programs are designed to be family-friendly and support infant and toddler health outcomes by providing rooms for mothers to nurse their infants and toddlers. Parents also

participate in advisory councils as well as serve on inspection teams to monitor child care quality standards.

The military model of child care emphasizes staff training and compensation. The system requires that all employees receive basic preservice training. Additionally, child care personnel begin with higher-than-average wages, and they are also rewarded with increased wages for achieving training milestones.

State Licensing, Monitoring, and Optional Accreditation

In general, states regulate early child care and education through licensing standards and monitoring practices. Many programs choose not only to incorporate standards that meet the required state licensing standards but also to adopt standards above and beyond minimal state standards. One organization, the NAEYC, is widely used by child care programs and is the largest organization serving on behalf of infants and children through age 8 in child care. The network was founded in 1926 with the mission of helping programs optimize child outcomes and to help families identify high-quality child care programs. It has an alliance of local, regional, national, and international affiliates. To be accredited by NAEYC, a program must involve itself in (a) self-study, through which staff identify areas for improvement; (b) validation, in which program information is verified during a site visit by a team of trained volunteers; and (c) a review by recognized experts who judge whether the program is in compliance with the accreditation criteria. Programs are granted accreditation for 3 years with agreement to improve areas in which they are only marginally compliant. Annual reports are required to document continued compliance and improvement.

Regulated and Process Variables in Early Child Care and Education

Both the U.S. Department of Defense and the Early Head Start programs are large-scale models with systematically incorporated standards above and beyond many state standards for infant and toddler early care and education. Many of the standards associated with these two programs come from NAEYC, the National Association for Family Child Care, or both.

Two types of variables are discussed in relation to early child care and education monitoring and evaluation: *regulated* variables and *process* variables.

Regulated variables encompass health and safety system variables, including adult-to-child ratios, group size, and staff education levels. Regulated variables matter to infant and toddler care in that they uniquely predict child development outcomes separate from other variables. Process variables relate to developmental outcomes in early care and education, both cognitive and socioemotional, which come from the relationship between providers of early care and education and the children in their care.

Regulated variables are predictive of process outcomes, which are related to child development outcomes. Thus, early care and education programs that have smaller adult-to-child ratios, smaller group sizes, and providers with higher education levels predict more positive provider-to-child social interactions. This, in turn, positively affects children's cognitive and socioemotional development. Thus, the most effective early care and education programs incorporate both highly regulated and process variables into services for infants and toddlers.

Family Contexts in Early Child Care and Education

Family features have been found to be the most predictive determinants to child development outcomes for children in early care and education settings. From these findings, models of early care and education have been established that emphasize the components of positive family features that can be replicated in early care and education settings. These process variables are associated with cognitive and socioemotional development by building secure relationships between early care and education providers and the infants and toddlers in their care. They include discreet aspects of emotional connections between care providers and infants and toddlers.

To develop emotional connections between care providers and the children in their care, the physical as well as interpersonal environment needs to be considered. Regarding the physical environment, standards call for a more home-like than school-like environment for infants and toddlers. To meet the needs of infants and toddlers, physical environments that replicate home environments often include primary caregiver assignments of one child care provider to a child. Additionally, infants are often allowed individual feeding and sleeping schedules and sleep in cribs among the rest of the group, rather than in separate sleeping

rooms. Children's work is displayed in the classroom and at child eye level to build a sense of ownership and belonging. Equipment, such as tables and chairs, is child-sized, and soft surfaces exist for children to rest and relax on during the day. A variety of materials exist, especially dramatic play materials, for toddler-age children to foster socioemotional and social skills development through role-playing behavior. Also, providers interact with the physical environment in ways that promote prosocial behavior, such as engaging in dramatic play activities and modeling and facilitating prosocial behavior between children. Last, a predictable environment with few changes to the setting is supportive of a child's emotional security.

In addition to the physical environment, socioemotional development in early care and education is also supported by way of emotional connections through caregiver–child interactions. An essential aspect of preparing child care providers to foster socioemotional development in the child is to learn about how to form emotionally available and securely attached relationships.

Attachment and Emotional Availability in Relationships in Child Care

Traditionally, attachment is viewed as a quality of parent–child relationships; however, children may also develop attachments with adult caregivers other than parents. Whereas approximately 70% of children form secure attachments with their parents, estimates indicate less than half of children in child care form secure attachments with their child care providers. The presence of caregiver sensitivity, appropriate structuring, nonintrusiveness, and nonhostility, which are qualities of emotional availability, are important, and research indicates that these qualities are predictive of secure attachments and children's emotional availability. According to Zeynep Biringen, caregiver sensitivity in the context of early child care and education includes both nonverbal and verbal behaviors. Nonverbal behaviors include physical affection, affect, awareness of timing, creativity during play, prompt and accurate responsiveness, and respectful behavior. Verbal behaviors include the provider mirroring what the child is doing, singing, and speaking to the child respectfully. Caregiver structuring behaviors that are nonverbal include not restricting the child in equipment such as a high chair longer than needed (or to the point where the child's patience runs out) and setting up individual and group activities. Verbal behaviors include talking to the child in passing, talking during meals and snacks, talking when picking up the infant to take to an activity (diapering), and verbally framing the transition from one activity to another. Caregiver nonintrusiveness behaviors that are nonverbal include picking up a child in a gentle way, limiting the number of physical interventions, reserving abrupt behavior for emergencies, not introducing all of the play toys, and playing with the child by focusing on an object that interests the child. Verbal behaviors include using language that is not intrusive, using a gentle and calming voice, and reserving language that can be jarring for emergencies. Caregiver nonhostile, nonverbal behaviors include attempts to be engaged with children rather than showing boredom and using coping mechanisms to limit stress. Verbal behaviors include limiting negative talk and refraining from complaining. Last, caregiver awareness of the child's contribution to interactions is evidenced by caregiver behaviors such as realizing that the child's emotions are linked with child–provider interactions; showing awareness that a child who is bland in facial expressions but causes no trouble and is undemanding is not a preferable presentation; and knowing that when a child is acting out, it is a communication mechanism. These nonverbal and verbal caregiver behaviors discreetly influence child socioemotional outcomes for infants and toddlers, specifically secure attachments, in the early care and education setting. Children with secure attachments are more likely to experience positive long-term outcomes throughout their lives. For that reason, children need caregivers who are emotionally available to them. Some of the benefits children may experience from emotionally available relationships are secure attachment, less aggressive behavior, less victimization, better peer relationships, more attentiveness at school, and better relationships with teachers. Early care providers must take into account the emotional and relational needs of infants and toddlers and facilitate emotionally available and secure relationships.

Despite the importance of the early child care context, new research findings from the National Institute of Child Health and Human Development (NICHD) Study of Early Child and Youth Development indicates only a small-magnitude linkage between child care and child development and that the family is more crucial than early care professionals in a child's development. Because child care has become an important resource and a way of life for working

mothers and fathers, it was important to conduct a definitive study to understand the impact of child care on children. For 15 years, a multisite investigation at 10 U.S. sites were examined, following the development of 1,000 healthy children and their families, beginning with a child's birth. Ethnically diverse families, with some 80% two-parent households, were initiated into the NICHD project. These children were in child care for close to 30 hours per week from birth to almost school age, thus including a sample of participants who had a high dose of child care in their infancy and preschool years. Most began in home-based situations with relatives or nonrelative caregivers and then progressed to center-based facilities.

An important finding from this multisite investigation is that children do better when parents are more educated; when income for the family is higher; when mothers are low on symptoms for depression; and when families have routines, rituals, books, and other learning and play materials. The children in the study had better outcomes if mothers were sensitive, and mothers were more likely to be so if they had more socioeconomically advantaged lives. These parent or family qualities were up to three times more strongly associated with child development than child care features, although when child care features were examined, qualities such as higher-quality care (with small child-to-provider ratios, good play materials, etc.) were found to be important. Those children who experienced high-quality care were more likely to have better social and cognitive (reading, math) skills than those who experienced low-quality care.

To bring a different perspective into focus, research on attachment has indicated that sensitive mothers are sometimes in relationship with insecure infants and toddlers. In such mismatched situations, "marginal" child care has been found to be a part of the equation. In a study conducted in Israel using the full spectrum of socioeconomic levels, infant attachment was assessed using the well-known Strange Situation procedure, and maternal sensitivity was assessed using the Emotional Availability Scales. Results showed that the hypothesized link between infant secure attachment and maternal sensitivity was found only for infants in individual care at home and not for infants at centers of low quality. It is possible to hypothesize that extensive experience in an early care environment that is not in tune with an infant's needs and that misses important cues for interaction and relationship may be akin to small doses of trauma. When an infant spends whole days where he or she is not responded to in an appropriate fashion and where engagement is lacking (on both the side of the professional and the side of the infant)—that is, where there is no real relationship—the infant may take back into the home setting behaviors that create insecure attachments to the primary caregivers as well. Thus, for children in child care, it is crucial to focus on both family and child care providers as agents of socialization.

In summary, emphasis on child care research should be to include parents as the primary socialization agents in their children's lives. Intervention science, however, should not abandon child care professionals as agents of socialization.

Early Intervention Programs

The term *early intervention (EI) programs* refers to a mosaic of services and programs created for young children and their families to meet educational, social, and health needs and promote enhanced learning, social, and communication outcomes. EI programs are provided before a child starts school, sometimes beginning before birth and continuing to school age. A goal of EI programs is to reduce gaps in child development that are due to one or more of the following: poverty or welfare status, family violence, child abuse, lack of family housing or ability to parent, poor health, single parenthood, teen parenthood, low maternal education, lack of proficiency in the English language, disabilities, developmental delays, poor language or emergent literacy, and the presence of a variety of at-risk conditions. EI programs incorporate a range of approaches, including child-focused interventions, dyadic interventions between an infant and parent, and family interventions that include siblings, parents, and even grandparents. The Division of Early Childhood for the Council of Exceptional Children identified a list of 1,606 recommended EI practices based upon a review of empirical research in 48 journals of effective early intervention programs or approaches.

Over the past 35 years, three major areas of interest have evolved in the field of EI programs:

1. Longitudinal experimental research of the efficacy of programs for children from birth to 3 years and preschool age

2. The national establishment of programs to achieve "equity" in education for children in poverty (e.g., Early Head Start and Head Start) and children with special health care needs or disabilities (e.g., Early Intervention Programs for Infants and Toddlers with Disabilities under Part C of the Individuals with Disabilities Education Act [IDEA] and Preschool programs under Section 619 of Part B, IDEA)

3. Concerns for quality and accountability prompted by legislative mandates

This entry will briefly highlight recent research in each of these interest areas and provide additional background information on modes of service delivery in health settings, homes, and centers and the economic advantages provided by intervention services.

Prevention Efforts

Early intervention programs may have features that are universal or are intended for a broad population. All young children are in need of a medical home that will provide continuity of medical care with developmental screening and preventive health care in a family-centered context. Model programs such as Healthy Steps, a pediatric care intervention, provide anticipatory guidance through child developmental surveillance, promote positive health practices, and encourage parents to ask questions and express any concerns they may have regarding their child's development. This program has proven successful in increasing a child's access to well-baby care, because participating families tend to remain with a practice for longer periods, and in reducing negative parenting practices and allowing depressed mothers a safe environment to discuss their distress.

Prevention approaches can begin even before the birth of a child in the form of preventing or ameliorating the effects of conditions that may be caused by environmental, lifestyle choices, or other addressable conditions. A number of early intervention programs have been developed that target women in the neonatal period, particularly women with conditions that require extended hospitalizations. The Newborn Individualized Developmental Care and Assessment Program (NIDCAP), developed by Heidelese Als and others, has fostered new approaches to neonatal care, especially among premature infants. The NIDCAP approach trains neonatal staff to support premature infant regulation and appropriate development through individualized observation. Because of recent technological advances, very low birth weight (VLBW) premature infants have an improved survival rate but are at higher risk for adverse health problems and developmental delays; neonatal intervention approaches like NIDCAP address these issues. As the rate of premature births continues to climb, the development of effective interventions for the medically fragile premature infant is of increasing concern.

Longitudinal Research Studies in Early Intervention

The U.S. Department of Education's Institute for Educational Sciences promotes experimental, randomized, clinical trials as the desirable method to determine efficacy in education. EI research has benefited from a history of longitudinal studies in which the infants, toddlers, and preschoolers receiving intervention services are now adults. The Carolina Abecedarian Project is a classic example of an EI study that demonstrates high methodological rigor, random assignment to intervention and control groups, and low attrition rates. This study of a model program, spanning 8 years, was designed to close the academic gap between young children from poor families and their more economically advantaged peers. In the first phase, full-day center-based services were provided to the intervention group from infancy to kindergarten entry, augmented by a developmental curriculum and an emphasis on language acquisition. From kindergarten to second grade, a home resource teacher supported and encouraged parents to work with their children at home. Participants continued to show consistent cognitive and academic gains compared with controls when assessed at 12-to-54 months and 12, 15, and 21 years of age. Participants in the preschool intervention had fewer retentions, were less likely to require special education services, and, by age 21, had completed significantly more years of education than controls.

Long-term follow-up programs contribute substantially to the field of early intervention, providing essential information on the types of developmental outcomes resulting from the application of models of intervention that vary based on format, content, intensity, and population served. Programs such as Chicago Child-Parent Centers and the Perry Preschool Project have yielded positive long-term outcomes through a combination of center-based and home-based parent-directed programs. In the case of the Perry Preschool Project, although significant gains on cognitive measures were not retained over time, real-life benefits included higher graduation rates and college attendance, improved rates of gainful employment, and reduced crime and teen pregnancy. Studies of specific populations, such as children exposed to cocaine, provide additional support for the beneficial effects of center-based programs in combination with home visits. A new area of promising research is the state implementation of universal prekindergarten programs for 4-year-olds, such as the efforts underway in Oklahoma, which provide encouraging findings of enhanced school readiness with significant gains in areas of math and language achievement. Finally, any mention of longitudinal intervention efforts must include a discussion of Head Start, the most widely offered early childhood program for preschool-age children living in poverty. Given the breadth and impact of Head Start and its companion program for children from birth to age 3, Early Head Start, each of these programs will be discussed in more detail in later sections of this entry.

Looking toward the future, the Early Childhood Longitudinal Studies-Birth Cohort, a nationally representative sample of 10,688 infants born in 2001, provides a prospective opportunity to study child development from infancy to kindergarten. In addition to comprehensive data about child health, family health and circumstances, and direct measures of a child's mental, motor, and social behavior, information about the provision of early intervention services and day care is also available. Eventually, analyses of these data could provide information that is relevant for national policies on children and EI programs.

Home-Based Programs

Within the field of EI, family-centered services are viewed as an integral component of successful programs. Offering services within a home-based setting has been found to contribute to a family-centered approach, as the child is treated within the family system, and caregivers have the opportunity to view and participate in the intervention activity. However, despite the extensive use of home-based services, little research has been done to evaluate the efficacy of this mode of service delivery for children with developmental disabilities. The field has not yet reached a consensus regarding the effectiveness of a home-based model of services, and some studies question the feasibility of implementing a home-based model within early intervention. In particular, concerns exist regarding the training and background of personnel, large provider caseloads, and the cultural mismatch between providers and participating families.

To date, few studies of home-based services document significant differences in participant versus control outcomes. For example, group differences were not found in home-based interventions aimed at improving parent–child interaction and positive parenting practices,

promoting child development, and preventing neglect and abuse. However, the negative findings must be placed in perspective, because to impact child outcomes over the long term, it is necessary to work directly with parents and primary caregivers to improve their ability to take better care of their children. In this regard, home-based services targeting parents and parents-to-be have proven to be effective. For example, research by Olds and colleagues as part of the Elmira Prenatal/Early Infancy Program provides evidence that home-based interventions lead to improvement in pregnancy outcomes, child health and development, and families' economic self-sufficiency.

In sum, given the inconsistent findings within the literature, the efficacy of home-based services has not yet been confirmed. However, the research has provided valuable information regarding some of the factors that limit program effectiveness, including infrequent home visits (i.e., due to cancellation or missed appointments), high attrition rates, urgent family needs that may interfere with program implementation, low parent engagement, heavy service provider caseloads, inadequate training of service providers, and a cultural mismatch between participants and service providers.

Disability: Birth to Three

In 1986, with the passage of Public Law (P.L.) 99–457, Education of the Handicapped Act (EHA), later renamed Individuals with Disabilities Education Act (IDEA), U.S. states had the option of establishing systems of early intervention services for infants and toddlers (i.e., from birth through age 2) with disabilities. All states and territories participate in this program and are asked to establish a coordinated and comprehensive system of services along with a method to ensure payment for early intervention services. EI services are multidisciplinary and uniquely designed to fully involve the child's family in the decision-making process through the development of the Individual Family Services Plan. The central focus on families is a distinct part of EI services both from a policy perspective and a programmatic stance. Thus, it is no surprise that most families receive services in the home, with speech, occupational, and physical therapies; special instruction; and developmental monitoring cited as the most frequent services delivered. The median amount of time for weekly services scheduled per child during the first 6 months in EI is 1.5 hours.

Children with diagnosed disabilities (such as Down syndrome) are automatically eligible for services, but states have discretion in the adoption of a definition of developmental delay and whether or not to serve children who are considered at risk for developmental delay. Variation in the eligibility criteria employed by individual states has resulted in variability in the percentage of infants and toddlers served in each state. In 2002, the most recently reported national count of children participating in Part C services ranged from 1% of the population to 9.38% with the overall average being 2.2%. Child characteristics are strongly related to the age at which children enter early intervention. Depending on eligibility criteria established within each state, children with specific diagnosed conditions and those considered at risk for developmental delay may automatically qualify for EI services and therefore, on average, are enrolled earlier than children with developmental delays. The low rate of early entry for children with developmental delays, including speech and language disorders, suggests the challenges of early identification of these disabilities.

National Early Intervention Longitudinal Study

The National Early Intervention Longitudinal Study (NEILS) is a longitudinal study of a nationally representative sample of the children and their families participating in early intervention services of Part C of IDEA. Beginning in 1997, data collection occurred at entry to EI through kindergarten; the data consist of family interviews, service record, and service provider, program director, and kindergarten teacher surveys. Recognizing the importance of family outcomes for young children with disabilities, NEILS found that families were highly satisfied with EI services, and nearly all families felt they were equipped to help their child learn and develop and believed they could advocate on their child's behalf. Although most families had positive experiences, ethnic minorities and families with children in poor health were more than twice as likely to have less positive outcomes.

In terms of child outcomes, NEILS found that children in EI vary widely in terms of their age-at-entry, health status, reason for eligibility, and pattern and level of developmental skills. Children identified as at risk and those with diagnosed conditions were found to enter much earlier than children identified with developmental delay. NEILS has shown that EI

entrants vary greatly in their developmental strengths and needs, reinforcing the importance of an individualized approach. As of kindergarten entry, one third of EI participants were no longer involved in special education and were not identified as having a disability. This finding suggests that a sizeable percentage of children enter EI with developmental problems, but given the appropriate support and intervention services, these children may avoid long-term involvement in special education. However, the majority of EI participants continue to require supportive interventions through preschool and/or school-age special education programs.

Disability: Preschool

P.L. 99–457, in 1986, also contained provisions in Section 619 to extend a free appropriate education to children with disabilities from the age of 3 to 5. Preschool-age children with disabilities are given the same services as older children in special education, including an Individualized Education Program. However, eligibility criteria for entrance into preschool special education often differ from the criteria established for EI. A challenge for states is to ensure that children in EI programs who need to continue receiving special services are not lost in the transition from the EI system to the school system. In addition, a major research question for the preschool population relates to the relative benefits of providing services in inclusive environments as opposed to segregated programs set up solely for children with disabilities. The preschool programs for children receiving special education from age 3 to age 5 can be in an array of settings, including public schools, Head Start, and other inclusive environments. In the 2002 child count of the preschool population under Section 619, about 30% of children were in inclusive early childhood settings, 39% in an early childhood or special education setting, 6% at home, 13% part-time in both early childhood and special education settings, 1% in a residential setting, 5% in a separate school, and the rest receiving itinerant services, and reverse mainstreaming.

Pre-Elementary Educational Longitudinal Study (PEELS)

The Pre-Elementary Educational Longitudinal Study (PEELS) was commissioned by the U.S. Department of Education to describe the school experiences, developmental characteristics, and educational programs of 3- to 5-year-old children participating in Section 619 preschool special education services. Preliminary study findings suggest that males are disproportionately represented, whereas the ethnic composition of preschoolers with disabilities tends to closely reflect the racial representation of the general population. Parental education level corresponds to that of the general U.S. population; however, a larger proportion of participants were reportedly living in poverty. Within the PEELS sample, approximately 50% of participants were eligible for services because of speech and language difficulties, with an additional 25% identified with developmental delay. PEELS found that approximately 25% of preschoolers with disabilities were born prematurely. On average, children in PEELS scored within one standard deviation of the mean on standardized measures of school readiness. However, wide variability was found across disability classifications. Children with mental retardation scored lowest on measures of verbal skills, whereas children with autism had more pronounced difficulties on measures of social skills and behavioral problems.

Poverty Interventions

Head Start

The Head Start program, administered through the U.S. Department of Health and Human Services, is a nationwide program targeting low-income families and their preschool-age children. In its four decades of existence, Head Start has provided child development and related services to over 23 million children. It offers a comprehensive array of services, including educational interventions, parental involvement, and medical services such as dental care and nutrition planning. Congress recently commissioned a study through the Department of Health and Human Services to document the population served in Head Start and determine Head Start's impact on school readiness and the conditions under which the program was optimally effective. The study sample consisted of approximately 5,000 children between the ages 3 and 4 from 84 nationally representative grantee or delegate agencies. At the time of service entry, participants were randomly assigned to either a control group (non–Head Start, receiving non–Head Start related services) or a Head Start program through which families and their children would receive Head

Start related services. Data collection started in the fall of 2002, and children were followed through the spring of their first-grade year. Findings reported at the end of the first year of data collection suggest a small-to-moderate impact of Head Start participation for both 3- and 4-year-olds. Across the four content areas examined (i.e., cognitive development, socioemotional development, health, and parenting practices) children with special needs showed improved outcomes in the areas of parent-reported child health status and receipt of dental care.

Early Head Start

Early Head Start is a program for low-income pregnant women and families with infants and toddlers up to the age of 3 years old. The program was designed by the Administration on Children, Youth and Families in 1994, and the first funds were received in 1995 and 1996. Early Head Start serves a wide array of families, operating in 664 communities and serving approximately 55,000 children. The program targets low-income families that include pregnant women, infants, or toddlers and aims to enhance the health and development of participants while strengthening community and family partnerships. In addition, since 1998, 10% of Early Head Start programs' funded enrollment opportunities must be offered to children with disabilities.

Overall findings of the Early Head Start Impact Report suggest that in the areas of language, cognitive, and social development, participants experienced a positive program impact compared with children in the control group. Participants were less likely to have delays in cognitive and language functioning and significantly more likely to receive Part C EI services than were control group children. However, this latter finding is contentious as some studies have shown that certain Early Head Start families were actually less likely to receive Part C services depending on family demographic characteristics, including ethnicity, linguistic background (i.e., non-English-speaking families), socioeconomic status (i.e., very low-income), and lower educational levels. Despite such findings, there is still wide-ranging support for the pivotal role that Early Head Start plays in connecting families with much needed services, such as those provided by Part C. Several studies have reported on Early Head Start service providers' efforts to assist families in learning how to navigate the system in order to access services.

In addition, Early Head Start staff offers guidance and recommendations to families with children with suspected delays or developmental disabilities.

Although much of the research on Early Head Start home-visiting practices has focused on typically developing children, the recent Early Head Start national study documents positive outcomes for young children with special needs. One explanation for the success of home-based services offered through Early Head Start may be tied to service individualization. By following Head Start performance standards that mandate weekly home-visits and bimonthly socialization, Early Head Start home-based services are tailored to meet each family's unique needs. When necessary, home-visitors provide additional comprehensive services and help to coordinate family service referrals. Positive parental outcomes included greater knowledge of child development, less parenting stress, ability of parents to provide a more stimulating environment at home, and more bedtime reading. In addition, families participating in Early Head Start home-based services were more likely to be involved in education and training activities. With respect to child outcomes, children receiving home-based services had better vocabulary development and were more engaged in playing with their parents or primary caregivers. Raikes and colleagues have noted three primary factors related to the success of home-based services on child outcomes: quantity (i.e., number of visits), quality (i.e., quality of engagement) and child focus (i.e., how much time was spent directly in child development-related activities).

When comparing home-based services to other service delivery options, it is important to bear in mind the complexities inherent in this form of service delivery. Vulnerable families living under stressful conditions are more likely to choose a home-based service option. This poses greater challenges for home-visitors, as some families have had prior unpleasant experiences with the service system. Families receiving home-based services are more likely to live in poverty and to consist of working and single parent families; in addition, young parents are overrepresented. Each of these factors potentially limits the time and effort that families are able to devote to early intervention activities. One study examining the impact of demographic risk factors on Early Head Start outcomes found that the program was less effective for families with more than three risk factors and that those families with the highest number of risk factors often receive home-based or mixed-approach services.

Standards for Evaluating Effectiveness

New federal and state accountability initiatives require that program expenditures be justified based on student educational gains. Early intervention programs, including those administered through Head Start, Maternal and Child Health, and the Department of Education, are not exempt from this scrutiny. Both Part C and Section 619 services of IDEA failed to demonstrate results under these Government Performance and Results Act requirements and were required to develop new outcome measures. The Early Childhood Outcomes (ECO) Center has assisted the U.S. Department of Education in adopting a functional outcome approach that will ultimately yield outcome indicators on three functional skill areas for each state over time. Developing valid and reliable outcome measures is a challenging yet fundamental task necessary for the accurate appraisal of program results. The ECO notes that misuses of data can result when overly narrow outcome measures are chosen, when additional outside information is not taken into account, or when data are misinterpreted.

Another way to judge the effectiveness of a program is to consider its costs relative to its benefits. Evidence is increasingly available supporting the cost-effectiveness of EI programs, highlighting their direct and indirect benefits to society. Some of the longitudinal programs that have been found to be cost-effective include Perry Preschool, the Abecedarian Project, the Chicago Child-Parent Center, and the Elmira Prenatal/Early Infancy Program. The returns from these programs range from $3 to $17 for every dollar invested. In addition, children in intervention groups were more likely to continue in regular education classrooms rather than special education, finish high school, and be gainfully employed.

Implications

To better understand the implications of successful EI longitudinal studies, it would be helpful to examine those interventions that have not produced the intended results. For example, the Early Head Start studies report that infants in families who benefit the most are those with no more than three risk factors (the neediest families would be among those with three to five risk factors). Shonkoff and others note that EI programs may need to be targeted more for children and families with complex social needs, including child abuse. This same reasoning can perhaps be applied to the very high risk populations being served by Early Head Start.

The Infant Health and Development Program, an experimental study of premature infants, offered well-structured center-based interventions that did not yield the expected results. When infants were divided into high and low birth weight groups, more robust gains were found in the cognitive outcomes of those infants considered low birth weight compared with the infants who were considered very low birth weight. These findings are of concern, as the early fragile medical status of very low birth weight infants puts them at high risk for long-term disabilities. Successful intervention efforts may need to be more intensive and individualized to positively impact this group. In addition to taking a more individualized approach to interventions, current best practice within EI includes consideration of broader issues, such as addressing the needs of the family within the context of the community.

To be effective, EI programs must be designed to address the needs of the population served. Three current trends impacting intervention services are the increasing rates of preterm births, child poverty, and a broadening of cultural diversity within the United States. To respond to these needs, broad-based programs are required to promote health prevention efforts focusing on early identification and intervention targeting prematurity and other risky health conditions. All EI programs are faced with changing cultural groups and the responsibility to tailor interventions to the needs of diverse linguistic, cultural, and sometimes national backgrounds. In European countries, tax structures and transfers have been shown to lower child rates of poverty; however, within the United States, poverty rates still exceed 20%, with increases noted in 2002 following a 9-year period of declining poverty rates.

EI programs have been built on the success of well-designed longitudinal studies. Going forward, all federal programs, including Head Start, Early Head Start, and Part C and Section 619 of IDEA, will be expected to produce clear developmental outcomes among children and families served in order to meet accountability standards. The complexities of child development and family issues may be difficult to capture in traditional government accountability processes. In addition, based upon the longitudinal studies from the past, it would be wise to examine

development and child and family impacts over the entire early childhood period. For example, a study that combined Early Head Start and Head Start experiences over time would be fruitful. Looking at outcomes of children with disabilities throughout the early childhood period (e.g., combining Part C and Section 619 of IDEA) would be a more meaningful picture of child readiness for school.

EATING DISORDERS

Eating disorders are psychological syndromes characterized by severe disturbances in eating behavior, typically in conjunction with intense fears of weight gain, distortion in one's perception of one's body shape and weight, and/or having a self-evaluation that is unduly influenced by body shape and weight. Eating disorders are of particular concern to educational psychologists because they typically onset in mid-to-late adolescence, and also because sociocultural and normative factors are strongly implicated in their etiology. In addition, some researchers believe that eating disorders may be best ameliorated through prevention programs targeted toward high-risk adolescents and delivered in educational settings. In this entry, the symptoms and diagnostic criteria for the two main eating disorder diagnoses—anorexia nervosa and bulimia nervosa—are presented first, followed by a description of the prevalence of, and gender differences in, these disorders and a description of a miscellaneous eating disorders diagnosis: eating disorder not otherwise specified. Next, the history, course, causes, prevention, and treatment of these disorders are reviewed. Finally, other eating disorder diagnoses are discussed, including tentative diagnoses that need further research, such as binge eating disorder, as well as feeding disorders of infancy and childhood.

Anorexia Nervosa

According to the *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision) (*DSM-IV-TR*), the psychiatric diagnostic classification system most frequently used by clinicians and researchers in the United States, to receive a diagnosis of anorexia nervosa (AN), an individual must maintain a body weight that is significantly less than normal. The *DSM-IV-TR* specifically states than an individual with AN must weigh less than 85% of the

weight considered normal for the individual's age and height; however, the *DSM-IV-TR* does not refer clinicians to a specific source to establish normal weight and, in fact, encourages clinicians to consider normal weight in light of individual factors such as body build. The current *International Classification of Diseases* (ICD-10), an alternative diagnostic classification system, specifies a more stringent standard for abnormally low body weight in AN; specifically, a body mass index of 17.5 or less.

To receive a diagnosis of AN according to *DSM-IV-TR* criteria, in addition to low body weight, an individual must also display an intense fear of gaining weight or becoming fat and a disturbance of certain weight- and shape-related thoughts. For example, an individual with AN may misperceive her body shape or size (believing she is larger than she really is), may use her weight as the only or the most important criterion against which she evaluates her self-worth, or may deny the seriousness or dangerousness of her low weight.

For women old enough to menstruate, the *DSM-IV-TR* also requires amenorrhea (absence of menstruation over several menstrual cycles) to make a diagnosis of AN. The reason for including amenorrhea as a criterion is that women who are abnormally thin or who have an abnormally low percentage of body fat frequently stop menstruating. However, because many women take hormonal birth control medications that cause regular menstruation regardless of body composition, this criterion can be difficult for clinicians to assess. Research also suggests that some women, even at very low weights, continue to menstruate, and several studies have found that deleting amenorrhea from the criteria does not reduce the quality of the AN diagnosis. For this reason, many researchers believe that amenorrhea will no longer be a requirement for a diagnosis of AN in the future.

After deciding that a patient meets criteria for AN, clinicians using the *DSM-IV-TR* for an eating disorder diagnosis must assign the individual to a subtype of AN. There are two subtypes: a restricting subtype and a binge-eating/purging subtype. Individuals who fall into the binge-eating/purging subtype of AN regularly engage in either binge-eating behavior, purging behaviors, or both (described more fully in the next section). Individuals with the restricting subtype of AN do not engage in such behaviors. Some people believe that anyone who engages in binge-eating or purging behaviors must have bulimia nervosa (BN), but this is not the case. The main feature distinguishing someone

with AN from someone with BN is body weight, not behavior; individuals with AN are abnormally thin, whereas individuals with BN are normal weight or overweight.

Bulimia Nervosa

BN is characterized by recurrent episodes of binge eating, followed by inappropriate compensatory behaviors designed to prevent weight gain, such as self-induced vomiting, misuse of laxatives or other drugs, periods of fasting, or excessive exercising. In the *DSM-IV-TR*, binge eating is defined as eating in a discrete period of time (e.g., a 2-hour period) an amount of food that is definitely larger than what most people would eat under similar circumstances and feeling a lack of control over eating during the binge episode. Some researchers call this definition an "objective binge" because the amount of food being consumed is objectively large, such as eating a half-gallon of ice cream or an entire extra-large pizza at a sitting. However, people with BN are more likely than objective raters to rate *any* given eating episode as a "binge." Researchers have also observed that the type of food consumed (e.g., foods perceived to be high calorie or "sinful," such as potato chips) and the individual's mood while eating are more predictive of whether an eating episode will be described as a binge than the actual amount of food consumed. Thus, some researchers believe the subjective aspects of a binge— the feelings of loss of control and negative emotions— may be more important to a diagnosis of BN than the "objectively large" binge criterion. However, other researchers maintain that the presence of objectively large binges has diagnostic significance.

In addition to binging, to receive a diagnosis of BN, an individual must engage in recurrent and inappropriate compensatory behaviors designed to prevent weight gain. Many people are aware of self-induced vomiting and laxative abuse as examples of compensatory behaviors engaged in by individuals with BN, but individuals with BN may also misuse other drugs, such as diuretics, diet pills, or enemas, or they may engage in periods of fasting, or they may simply exercise excessively. Exercise is considered "excessive" when it interferes with other important activities, such as schoolwork or relationships; when it occurs at inappropriate times and places; or when the individual continues to exercise despite injury. Individuals must engage in both binges and compensatory behaviors,

on average, twice a week or more for 3 months to receive a diagnosis of BN. In addition, similarly to individuals with AN, individuals with BN must be unduly influenced by their shape and weight in evaluating themselves.

As with AN, BN is divided into two subtypes: a purging subtype, where the individual engages in self-induced vomiting or the misuse of drugs to prevent weight gain; and a nonpurging subtype, where the ways that the person has tried to prevent weight gain have included only other methods, such as fasting or exercise. Some people may believe that someone who does not use laxatives or self-induce vomiting cannot have BN, but this is not the case.

Gender Differences, Prevalence, and Subthreshold Cases

Both AN and BN affect women disproportionately; 90% of people who meet criteria for either diagnosis are female (hence the convention in this entry to refer to individuals as "she"). Men do acquire eating disorders, however, and men and women with eating disorders appear to have similar symptoms, similar risk factors prior to developing the eating disorder, and similar co-occurring disorders (such as depression). Compared to women with the disorder, men may have a later onset of their eating disorder symptoms and may be more likely to have engaged in a sport where weight control was emphasized or to have been overweight prior to the onset of the disorder. Some researchers believe that eating disorder rates in men may be increasing as sociocultural pressures on men to be thin and athletic-looking increase.

Even in women, AN is relatively rare, with a lifetime prevalence among women of 0.5%. Bulimia nervosa is somewhat more common, with a lifetime prevalence among women of 1% to 3%. However, these may be underestimates of the true prevalence of eating disorder pathology. One serious criticism of the *DSM-IV-TR* classification of eating disorders is that the majority of patients seen in clinics who present with eating disorder symptoms do not actually meet full criteria for either AN or BN. People who have serious eating disorder symptoms, but who do not meet full criteria for either AN or BN, are usually diagnosed with eating disorder not otherwise specified (EDNOS), a miscellaneous diagnostic category that includes people with a wide variety of eating disorders symptoms and symptom severity. Little is known about how people with EDNOS differ from people with AN or BN, but they can have symptoms equally as severe as those who meet criteria for the full disorder. In one study of hundreds of patients who had sought treatment at eating disorder specialty clinics in several states, the percentage of patients who were diagnosed with EDNOS instead of AN or BN ranged from 49% to 71%. In other words, the relatively low prevalence of AN and BN may not reflect the true number of people who are troubled by serious eating disorder symptoms.

History of Eating Disorders

As far back as the Middle Ages, writers have described occasional cases of individuals, often young women, deliberately engaging in self-starvation, typically as part of religious devotion. In 1689, the physician Richard Morton described two cases wherein a young person (he described both a male and a female patient) under significant psychological stress refused to eat and became abnormally thin. His medical interventions with these patients were apparently of little benefit, and his female patient died (it is unknown what happened to his male patient following treatment). However, these early cases, however much they may resemble AN, lack the preoccupation with weight, shape, and avoidance of fatness that is the hallmark of the modern disorder. A description of the disorder in its contemporary form, including the association between self-starvation and fears of fatness or disturbed body image, as well as psychological distress, began to appear in accounts of the disorder at the beginning of the 20th century. BN, in contrast, has a much shorter history. Although there exist a small handful of case reports of binge-eating and compensatory vomiting or laxative abuse as early as the 1940s, the disorder was not named until Gerald Russell described it as a variant of AN in 1979. At that point, there were sufficient cases to mount a research program on the disorder, but it seems clear that BN largely appeared as a new disorder in the latter half of the 20th century.

Course of Eating Disorders and Relations Between Disorders

Eating disorders are often medically serious and can become chronic, although in some cases they also

remit, with or without treatment. The onset of both AN and BN is typically in mid-to-late adolescence, although AN usually begins slightly earlier than BN, and an onset for either disorder in early adulthood is also not uncommon. With respect to AN, a total recovery, with normal body weight, normal body image, and no intense fears of weight gain, is rare. Fewer than 50% of individuals with AN achieve recovery, defined as normal or near-normal body weight, resumption of normal menstruation, and eating patterns free of severe dietary restriction, binging, or purging. Even among these "recovered" individuals, however, distorted body image, ongoing fears of weight gain, and other psychological symptoms of eating disorders often continue. Although treatment for AN can be lifesaving in the short term, long-term recovery rates are not markedly improved for treated versus untreated individuals. About one third of individuals with AN can be expected to improve somewhat, while still displaying serious eating disorder symptoms, whereas about 20% continue to meet full criteria for AN even years later. The mortality rate for individuals diagnosed with AN is extremely high: about 5% per decade of follow-up, higher than for any other mental disorder except heroin dependence. Most deaths associated with AN are either the result of suicide or medical abnormalities that arise as a consequence of starvation. Suicide risk for individuals with AN is higher than that for any other mental disorder.

The prognosis for an individual with BN is overall more encouraging, although the course of BN also is frequently chronic. Between one third and one half of individuals with BN continue to meet full or partial criteria for BN in long-term follow-up studies, although effective treatment (discussed in more detail later in this entry) appears to improve the course of BN. Less is known about the course of EDNOS; one study that followed individuals who met partial but not full criteria for eating disorders found that most still struggled with symptoms 3 years later. In fact, nearly half of these participants went on to develop either AN or BN by the end of the study. In other words, the EDNOS category includes individuals who do not necessarily have a less severe eating disorder and who may go on to develop either AN or BN.

As this discussion makes clear, moving between eating disorder diagnoses is common; people initially diagnosed with AN frequently go on to develop BN, although an individual with BN subsequently developing AN is somewhat less common. Also, many individuals with AN or BN improve somewhat while still retaining significant eating disorder symptoms, thus meeting criteria for a subthreshold eating disorder, often classified as EDNOS.

Causes of Eating Disorders

Genetic Influences

Twin studies estimate the degree to which genes influence the development of disorders by comparing monozygotic (or identical) twins with dizygotic (or fraternal) twins to see if both members of the twin pair have a history of the disorder. When both members of a twin pair have (or do not have) a disorder, this is called *concordance*. If monozygotic twins are more likely than dizygotic twins to be concordant for a disorder, researchers consider this to be evidence that the disorder has a genetic component, because both monozygotic and dizygotic twins presumably share a family environment, but only monozygotic twins also share all of their genes. Twin studies in eating disorders find that concordance rates for monozygotic twins are higher than rates for dizygotic twins in AN, suggesting that vulnerability to AN is heritable. However, monozygotic and dizygotic twins have similar concordance rates in studies of BN, suggesting that a specific vulnerability to BN is probably not heritable.

Family studies, where researchers look for evidence that a given problem runs in families by researching the relatives of people who have a given disorder, have revealed that eating disorders run in families, such that families with one person who has AN are more likely to have other members who also have AN, BN, or other eating disorder pathology. In addition, in the case of individuals with either AN or the binge-purge subtype of BN, family members are more likely to suffer from substance abuse or dependence, as well as depression. Viewed as a whole, the family and twin studies of eating disorders suggest that there may be a specific genetic vulnerability for AN and a more general genetic vulnerability to psychopathology that influences a range of psychological problems, including BN.

Family Influences

Certain specific aspects of a child's upbringing or life experiences prior to developing an eating disorder have been implicated as risk factors in eating disorders.

These include some eating and appearance-related factors, such as having parents who are themselves dieting or who are critical of the child's appearance. In addition, family risk factors less obviously related to appearance or food have also been identified, including parents who are frequently absent or underinvolved in the child's life, parents with high expectations for the child or who frequently criticize the child, and discord or conflict between the parents. Experiences of abuse have also been implicated as risk factors for eating disorders; sexual abuse has been most frequently researched as a risk factor, but physical abuse and neglect of a child also appear to be important.

Dieting

Interestingly, the practice of dieting may contribute to eating disorders, specifically by increasing the risk of symptoms of binging and purging. Early indications that dietary restriction could lead to eating disorder symptomatology came from a famous study conducted by physician Ancel Keys and his colleagues during World War II. The goal of the study was to understand how to best treat starvation in war victims, and the research was conducted on 40 men who had been pre-screened for exceptional physical and psychological health. During the study, these men underwent a 24-week period of semi-starvation. Many of the men developed severe psychological symptoms and abnormal eating patterns during the course of study, including binge-eating, food stealing and hoarding, severe depression, and even psychotic symptoms. A remarkable 50-year follow-up found that fully 25 of the original 40 participants (all who consented to be interviewed) reported ongoing abnormal eating behaviors and ruminations related to food that had persisted even a half-century later.

The role of dieting in abnormal eating behaviors is further supported by experimental studies, which have demonstrated that when dieters are given a high-calorie food, they tend to consume more of it than do nondieters. They also fail to regulate their food consumption in an experimental setting; whereas nondieters will eat less of a high-calorie food if they have eaten a high-calorie food earlier, dieters eat more of the high-calorie food than nondieters do on both occasions. Such research suggests that dietary restriction under some circumstances may encourage binge behavior, which then may encourage purging. Several longitudinal studies have provided support for this view by establishing that dieting behavior predicts later onset of eating disorders, particularly BN.

Sociocultural Factors

One major factor implicated in the etiology of eating disorders is a cultural emphasis on the "thin ideal," or an unattainably slender figure as a standard of beauty (especially female beauty, although many researchers believe that cultural pressures on men to meet an unattainable physical ideal are also increasing). Eating disorders are rare or unknown in cultures that do not place an emphasis on thinness as a virtue or a standard of beauty; research suggests that eating disorders increase in prevalence when cultures begin to adopt a thin ideal or among individuals migrating from a culture that does not endorse the thin ideal to one that does. Eating disorders also appear to have increased dramatically in prevalence in Western countries as thinness has increased as a cultural ideal. For example, examining the weight and body size of both Miss America winners and *Playboy* centerfolds reveals a trend for decreasing weight over the past 50 years in women featured in these venues. Weight loss articles published in magazines have also increased over the same time frame, as has the prevalence of eating disorders. Some researchers believe that BN, not described until 1979, is more causally linked to sociocultural pressures than is AN, which has appeared in some form in many time periods and cultures and which appears to be more strongly heritable. Experimental research varying participants' exposure to the thin ideal (by having some participants look at pictures of thin models or receive fashion magazine subscriptions) also suggests that participants' body dissatisfaction and internalization of the thin ideal (as well as feelings of depression) increase with exposure to thin ideal media images. Longitudinal research shows that body dissatisfaction and thin-ideal internalization, in turn, are related to increased eating disorder symptoms.

Many researchers, however, have observed that whatever the overall influence of sociocultural pressures on eating disorder prevalence and symptoms, exposure to social pressures to be thin is not sufficient to cause eating disorders. If it was, most people exposed to such pressures—most people living in Western cultures—would have eating disorders. This is not the case. Researchers therefore have developed several integrative causal models of eating disorders that typically combine biological influences, individual

characteristics, familial and social pressures, and dieting behaviors to predict the acquisition of an eating disorder. Researcher Eric Stice and his colleagues, for example, developed an influential dual-pathway model of BN that posits that bulimic symptoms are caused by dieting, negative emotions, and the interaction between them, which in turn are caused by body dissatisfaction caused by pressures to be thin and the degree to which one has internalized the thin ideal. Other influential models emphasize biological and genetic characteristics, personality characteristics (such as perfectionism or need for control), or cognitions related to weight and shape.

Prevention and Treatment

Eating disorders are difficult to treat. Although inpatient treatment of AN does result in temporary weight gain as a result of refeeding of patients while they are hospitalized, no treatment, medical or psychological, has definitive proof of efficacy in treating AN long term. A new form of family therapy for AN, the Maudsley approach, has shown a great deal of initial promise as an efficacious treatment for adolescents with AN, with as many as 90% of adolescents treated with this approach achieving long-term recovery from the disorder in clinical trials. However, as the treatment focuses primarily on empowering parents to work with their children in stopping the disorder, it may not be suitable for adults with AN, and research on this approach is still ongoing.

In contrast to AN, several treatment approaches are known to be efficacious in addressing BN. Specifically, both cognitive-behavioral therapy (CBT) and interpersonal psychotherapy (IPT) have good empirical support as efficacious treatments for the disorder. In CBT, clinicians focus on altering eating disorder behaviors and cognitions through challenging irrational beliefs related to shape and weight and through monitoring and changing binging and purging behaviors using behavioral techniques. In IPT, clinicians focus not on the eating disorder behaviors per se, but instead on helping patients identify and modify their current interpersonal problems. Both CBT and IPT appear to be equally efficacious in treating BN, although patients receiving CBT appear to improve more quickly, and CBT has been more extensively researched. Although both therapies are superior to other treatments for BN (such as antidepressant medication) for the average patient, only about half of the

patients treated with these treatments cease binging and purging. Thus, there remains a great need for further research to identify treatments that will help those who do not improve.

Because eating disorders can be so serious, and the currently available treatments are so limited, many researchers have focused attention on preventing instead of treating them. Prevention programs vary in their effectiveness. Ineffective prevention programs are primarily those which are shorter in duration (e.g., only one session in length), which present material in a didactic (rather than interactive) style, or which focus on educating participants about the disorders. More effective programs, in contrast, target individuals who are at high risk for the disorders, last longer than one session, and use interactive teaching methods. In addition, effective programs focus on helping participants change their level of body dissatisfaction or internalization of the thin ideal or other factors thought to cause the disorders, rather than merely providing participants with information about the disorders. Some of the most effective prevention programs actually do not describe themselves as eating disorder prevention programs at all but instead are described as body acceptance programs, emphasizing the focus on underlying causes of eating disorders. One promising and effective approach to prevention focuses on increasing participants' discomfort with the thin ideal by asking them to dissuade others from adopting this ideal. Although prevention approaches must be carefully designed to be effective, they show great promise in decreasing eating disorders. Many researchers believe that persuading media outlets to adopt a more realistic ideal of beauty might be the most effective means of prevention of all.

Other Eating Disorders

Although AN, BN, and EDNOS represent prototypical eating disorders, other problems related to eating have been identified. These include both *DSM-IV-TR* disorders, such as the eating disorders of infancy and early childhood, and disorders that have been designated as deserving of further study, such as binge eating disorder (BED). BED consists of recurrent and frequent episodes of binge eating as in BN. In BED, these episodes of binging are related to feelings of distress and other problems in living, such as obesity, but unlike in BN, the individual does not engage in any compensatory behaviors to prevent weight gain and may not

experience any distortions of body image or fears of fatness that are central to the other eating disorders. Little is known about BED compared with the other eating disorders, but there are important differences between BED and the other eating disorders. Individuals presenting for treatment of BED tend to be older than those with AN or BN (in middle age rather than adolescence) and are more frequently male (as many as 25% are male). In addition, although BED seems to be associated both with obesity and feelings of depression, the distress and risk associated with the disorder may be less acute than in AN or BN. In addition, it is not clear how individuals with BED who seek treatment differ from individuals who routinely overeat but do not experience distress related to overeating.

Even more distinct and unrelated to the prototypical eating disorders are the eating and feeding disorders of early childhood, which include pica, rumination, and feeding disorder of infancy or early childhood. Pica consists of repeatedly ingesting inedible substances, such as paint, plaster, sand, or soil, in a fashion that is inappropriate to the person's developmental level and culture. Rumination consists of repeatedly regurgitating and rechewing food after feedings. Feeding disorder of infancy or early childhood consists of a child younger than age 6 failing to eat adequately and consequently losing weight or failing to gain weight. None of these disorders is associated with fears of fatness or concerns about body image. In most cases, these disorders are associated with mental retardation or developmental delays, a lack of an appropriately enriching or nurturing environment, or child abuse or neglect.

EDUCATIONAL TECHNOLOGY

Educational technology can be thought of as the hardware, software, and "thinkware" of learning, as well as related research theory that guides these efforts. This entry first defines what educational technology is. Next, it presents a short history of the field. Then it presents highlights of the hardware, software, and audiovisual technologies used by educational technologists; processes and theories used by educational technologists; and research in educational technology.

What Is Educational Technology?

Educational technology is "the study and ethical practice of facilitating learning and improving performance by creating, using, and managing appropriate technological processes and resources," according to the Association for Educational Communications and Technology (AECT), the largest professional society focused solely on educational technology.

In practice, that encompasses several distinct areas of effort. One is planning and installation of technology for education. Since the mid-1970s, this technology has increasingly meant the computers used to teach and manage learning and related activities, but it also includes other hardware and operating technologies, from film and audio equipment to LCD projectors and other sophisticated projection systems.

A second area of focus for educational technologists is educational software. Some educational technologists develop learning programs that can be taken on a computer. These programs can be *synchronous* (occur when learner and instructor are both online at the same time, such as in a chat) or *asynchronous* (instructor or learner are not online at the same time, such as in a self-study tutorial). Other educational technologists develop software tools that are used to develop these learning programs, such as *virtual classroom software* (like WebEx and Centra), used to provide synchronous learning experiences, and software for creating tutorials, called *authoring tools* (such as Dreamweaver Course Builder and Authorware). This software focus is reflected in the definition of educational technology offered by the International Technology Education Association (ISTE): "Using multimedia technologies or audiovisual aids as a tool to enhance the teaching and learning process."

A third focus of educational technologists is the processes and products used to design instruction. In these applications, technology refers to the sequence of activities and the applications of cognitive psychology to the design of instruction, rather than a physical hardware or a type of software. These activities are known as *instructional-design*, as phrased by Charles M. Reigeluth.

In terms of academic study, educational technology is available as an academic degree from universities in nearly every U.S. state, as well as in Australia, Canada, the United Kingdom, and several countries in the Middle East and Asia. In its most academic form, educational technology explores the following: the models and processes used to analyze, design, develop, deliver, implement, and evaluate instruction; the technology used to support these processes—both analogue and computer-based—in order to deliver learning materials, facilitate communication, and provide assessment and feedback; the policies associated with these practices; and the research that informs practice.

The academic study of educational technology explores learning throughout the life cycle, from preschool through retirement education. Similarly, because educational technology encompasses technology, learning, and design, it is an interdisciplinary field that draws upon other fields such as educational psychology, developmental psychology, early childhood and elementary education, higher education, adult education, computer science, ergonomics, sociology, and communications studies.

History

Educational technology emerged as a field in its own right in the 1920s, though some point to the initial development of human communications as one of the first developments in educational technology, because these facilitated the exchange of knowledge between members of tribes and from generation to generation. The invention of writing and writing instruments, such as papyrus and pens, further facilitated that process.

Modern educational technology charts its roots to the advances in media occurring in the late 19th century, such as inventions of visual and audio recording and playback devices. Soon afterward, each found its way into education, as educational films (the first appeared in the early 20th century), educational records, and the use of photographs in textbooks.

During the 1920s and through the 1940s, with advances in other media, such as audio recordings, radio, and motion pictures, the focus shifted from visual instruction to audiovisual instruction. This trend continued through the 1950s with the advancement of television. At this point in time, educational technology focused primarily on the use of instructional media, and the field was commonly known as *instructional technology*. In the 1950s, and most notably in the 1960s and 1970s, educational technology became more and more complex. It grew from a discipline concerned primarily with instruction using audiovisual aids to one concerned with systematic instructional design. At the same time, the field of education began to see instructional technology as a process that looks at instructional problems and explores solutions to these problems.

As technological advances exploded with the computer revolution, educational technology became a complex, integrated process that became increasingly professionalized. The AECT developed a new definition of the field in 1977 that included the importance of the planning and analysis phases of instructional design. This definition also included a list of learning resources and clarified terms such as learning problems

and solutions. This new definition emphasized that instructional technologists were interested in more than just the development and use of media. The discipline began to attract individuals from various disciplines.

With the growth of the microcomputer, Internet, interactive video, and other communication technologies, educational technology has become accessible to the general public and to most organizations. In addition, behavioral learning theories, which previously served as the basis of instructional design, gave way to cognitive and constructivist theories. These developments led to a growing interest in the development of instructional strategies that incorporated these new developments. As a result, in the mid-1990s, a new definition of educational technology emphasized the main areas of study and practice in the field; design, development, utilization, management, and evaluation. The interrelationship of these domains emphasizes the link between teacher, learner, and instructional method. The profession is now more concerned with the application of a variety of instructional techniques, ranging from traditional lecture approaches to open-ended distance learning environments.

In the new millennium, the field has continued to grow and change as society and learners evolve. The number of universities and the expansion of mass education along with the inadequate funding provided by governments, as well as the increasingly heterogeneous background of learners, are just some of the challenges. Increasing numbers of knowledge workers are seeking jobs that correspond to new job requirements. With the Internet, there has been an explosion in the volume of information and potential knowledge available. All of these advances have led to a more individualized type of education that is geared to specific needs, an education that is sometimes distance-oriented but primarily subject-specific. As technology becomes increasingly complex, there is a greater need for professionals who are able to train and help users become adept and skillful in the use of the new technologies.

Although many in the field continue to work on media and tasks related to the instructional process, many work in processes that are influencing the world as a whole. As the world outside the university changes dramatically, there is an increased demand for highly skilled workers, who need to be continually learning and improving their professional technical skills. As a result, educational technologists have been paying more attention to improving workplace performance and knowledge management. As the academic world gradually adapts to the real world of technological and societal changes and lifelong learning becomes critical to economic growth and development, the field of educational technology responds. There is an increased emphasis on independent learning, on developing social skills and teamwork, on adapting to change, and on developing thinking and problem-solving skills. As the volume of available information expands, it has become increasingly important to develop systems that can help people get at and process this information. Educational technologists are active in all these various areas.

Hardware, Software, and Audiovisual Technologies

One area of focus within educational technology is the applications of technology in learning. Technologies generally fall into these categories:

- Technologies for teaching and learning
- Technologies for facilitating communication among participants in the learning process
- Technologies for facilitating evaluation
- Technologies for managing learning activities

Because standardization of technology is essential to the smooth integration of technology in education, any discussion of technology also addresses standards.

Technologies for Creating Learning Materials

Some argue that the first educational technologies include writing systems, papyrus, and the writing instruments on which to place characters on the papyrus. One of the purposes of ancient documents was to record history and key lessons so that future generations might learn from them.

But the modern practice of educational technology begins with the introduction of audiovisual technology in the late 19th and early 20th centuries. The technologies can be categorized as follows:

Technologies for designing and developing the materials. Most of these technologies were developed for assisting with the creation of content. One of the earliest technologies was the typewriter, which enabled people to create content faster, more legibly, and more consistently. Later versions of typewriters included the ability to correct errors, change the look of the typeface, and save content, so revisions would not require retyping. The advent of computers brought

about word processing, software that lets authors write, change, revise, and print text; desktop publishing, which allowed the low-cost production of high-quality educational materials (before that, material was prepared by hand with highly skilled labor); and software for publishing materials online, including the HTML standard that lets Internet browsers like Mozilla Firefox and Internet Explorer display content produced from a variety of sources. Whereas none of these technologies was specifically produced for educational purposes, there was one that was: the authoring system, which is used to create online learning programs for people with little or no knowledge of computer programming. This software lets authors not only create the content but also determine what it looks like and test learners' understanding of the content. One of the first major authoring systems was PLATO; it appeared in the late 1960s and was intended for mainframe computers. In the mid-1980s, several key authoring systems for microcomputers emerged, including the Hypercard for the Apple computer, which also had other purposes and was intended for people with limited computer literacy, and Authorware, which was more sophisticated.

Technologies for producing the materials. This category includes equipment for recording visual images (photography, film, and video cameras, as well as related lighting) and audio (sound recorders, microphones). It also includes equipment for developing photographs and editing visuals and sounds together into a single, coherent product. In the past, this equipment worked with analog technology. Since the early 1980s, recording and production have converted to digital technologies. Note that these technologies were not developed specifically for use by educational technologists. However, the price consciousness of many educational technology departments provided incentives to manufacturers to develop more modestly priced versions of this equipment.

Technologies for reproducing the learning materials, which involves making copies of audiotapes, films, books, articles, and similar materials. These technologies were not developed specifically for educational technologists, and many educational technologists use outside companies to handle these tasks (and, therefore, have limited exposure to them).

Technologies for playing the recordings or using the content, which involves the use of specialized

projectors and similar playback equipment that often cost thousands of dollars. For audio, playback equipment includes record, tape, CD, and MP3 players. For visual recordings, playback equipment includes filmstrip and slide projectors. For combinations of audio and visual recordings, playback equipment includes film projectors and screens and video players and monitors. Audio and visual recordings have also been synchronized, such as slide-sound shows in which a slide projector automatically advances a slide show when it hears a special sound from a tape recorder. More recently, playback is available on computers, personal DVD players, and personal digital assistants, like PalmPilots and iPaqs. Playback equipment also includes equipment for projecting these visual images so large audiences can see them. Projection equipment includes screens, LCD projectors, large screen monitors, and rear-projection systems. Although none of these technologies was developed specifically for the educational environment, versions of the products were adapted specifically for educational environments.

Most of the technologies for creating learning materials require specialized knowledge. As a result, the curricula of many academic programs in educational technology programs include components on the use and operation of this equipment.

Technologies for Facilitating Communication Among Participants in the Learning Process

A second group of educational technologies is intended to facilitate communication between instructors and learners. These technologies can be categorized as follows:

Technologies for facilitating communication among the participants in the learning process. In the late 19th and early 20th century, these technologies primarily included mail and telephone. Both types of communication were intended for person-to-person communication. With the advent of computer-based technologies, several new options emerged. Some provided for person-to-person communication, including electronic mail (e-mail), Internet telephony, and instant messaging (IM). Other options offered by the computer included group-based communication. Early options included discussion lists (also called listservs, which are ongoing e-mail exchanges among a group of registered participants) and discussion boards,

programs that manage discussions on a class of topics. With the advent of social computing on the Web are wikis, which allow a group to rapidly create a work product together online, and blogs (short for "web logs"), which are like online columns from a newspaper or diaries, and to which readers can leave comments.

Technologies for replicating the classroom through technology. These technologies allow students to participate in class when they might not otherwise be able to, because of physical condition, time constraints, or geographic constraints. Early technologies for replicating the classroom include radio (such as the bush radio used in Australia) and conference calls by telephone. By the mid-20th century, television classrooms emerged (in fact, the use of television for learning was one of the reasons for establishing the U.S.-based Public Broadcasting System, as well as several academic educational technology programs, like the one at Concordia University in Montreal, Canada. Although some uses of television were based on public broadcast, private, closed circuit television systems also were used, such as the University of Minnesota's UNITE system and IBM's Interactive Satellite Education Network. Most closed circuit networks had two-way communication ability, which means that not only could students see and hear the instructor, but the instructor could see and hear the students. By the mid-1990s, software had been developed that allowed educators to create a classroom-like environment online. Called virtual classroom software, this software lets instructors speak, show images, and interact with students in large and small groups and lets students interact with their instructors.

Technologies for Facilitating Evaluation

A third group of educational technologies is intended to facilitate the process of evaluating the learning process. A technology from the latter half of the 20th century is Scantron, which lets instructors automatically grade exams with objective questions (true/false, multiple choice) by having students fill out a form that can be read by the grading machine.

Most of the developments in this area of educational technology occurred after computers came into common use. Some of these technologies focus on grading a particular assignment. One is software that conducts entire tests online. Original versions of this software limited educational technologists to objective questions, but later technologies have allowed instructors to

ask open questions (like essay questions) online. In most instances, instructors need to grade those answers themselves. Although some software has been developed to grade open questions, it is not yet in common use. A related technology lets instructors assess the likelihood that an essay or similar written assignment is plagiarized.

Other computer-based technologies for evaluating learning focus on broader issues. Portfolio software lets learners create a process portfolio, which allows them to include a class assignment and comment on what they learned from the assignment. An instructor, advisor, parent, or peer can review the assignment and reflections and offer feedback. Another is analytics software, which lets an administrator or manager compile statistics from a variety of computer-based sources, such as information about students, enrollment, and grades, and identify larger trends in the operation. Some of these analyses are presented as dashboards (e.g., the analysis of the American Society for Training and Development), which look like the dashboard of a car with a large number of indicators. When a problem seems to be arising in one of the indicators, the system visually signals the manager by turning that indicator red or orange.

Technologies for Managing Learning Activities

A fourth group of educational technologies is intended to manage learning activities. These technologies assist with the management of class activities as well as broader activities of the organizations that sponsor learning. Technologies for managing learning activities include learning management systems, course management systems, and learning content management systems.

Learning management systems. Learning management systems (LMSs), which act as electronic registrars, perform some or all of the following tasks for both online and classroom courses:

- Registration
- Tracking of participation (classroom attendance, sign-ons and sign-offs of online courses)
- Tracking of completions (including final scores or grades)
- Testing
- Providing aggregated reports, such as the numbers of people registered for particular courses

- Sharing information with other systems, such as human resource information systems
- Suggesting curricula for learners
- Tracking skills of individuals and groups of people within an organization
- Providing learners with a one-stop shop for their learning needs (especially online programs) and personalized information, such as a customized learning page that includes recommended paths through learning material

Examples of LMSs include Saba, Plateau, and NetDimensions EKP.

Course management systems. Course management systems (CMSs) were originally designed to support classroom learning in academic settings, such as universities and high schools. CMSs provide instructors with the ability to do the following:

- Place course materials online. Most CMSs provide preprogrammed buttons for the course syllabus, course schedule, and course materials linked to specific lessons, such as copies of readings and Power-Point slides from lectures.
- Track student progress, through assessment features (which let instructors give quizzes and tests online) and an online gradebook, where instructors can post student grades.
- Discuss readings with students and continue class discussions between formal class sessions, through the use of a discussion board.
- Send announcements to classes and communicate individually with students.
- Provide a lock box for students, where students can store class materials (e.g., a presentation to give later in class).
- Track course statistics, such as who used the course site and when.

Examples of CMSs include the commercial products Blackboard and WebCT and the open source system Moodle.

Learning content management systems. Learning content management systems (LCMSs) are software for creating, storing, retrieving, changing, and reusing material intended for use in an online learning program. LCMSs also store test questions and can be used to track activities in developing material. Finally, LCMSs can format the same content for presentation online and in print, and with a number of word processes. Examples of LCMSs include Eedo Force 10

and OutStart. Note that many LCMSs also have the registration and management functions of an LMS.

Standards for Learning Technology

Standards refer to rules that have been set up by various professional and trade organizations to address a variety of aspects of the development and production of learning content, so that content produced in one organization and on one brand of equipment can be easily used in another organization on another brand of equipment. Although all types of learning technologies involve the use of standards (e.g., how to take a photograph and ensure that the slide projector plays it), standards have only become a significant concern to educational technologists with the advent of online learning.

In technology for learning, a standard represents the last phase in a series of milestones intended to develop an idea for coordinating interactions among software and devices. The first phase results after someone or a group of people recognize a situation in which some coordination of efforts will result in more efficient or economical interactions among programs or some similar benefit to users. In many ways, this idea is similar to that proposed by Geary Rummler and Alan Brache for human performance technology. They note that efficiencies and improvements are often achieved by examining and reengineering the interactions among groups within and across organizations.

Processes and Theories

The field of educational technology is guided by a family of processes that form the core of most academic programs and are widely acknowledged by most practitioners. These processes are also part of introductory training to people who work in the field but do not have academic backgrounds in the field.

The core process followed by educational technologists is known as *instructional systems design*, which is the recommended process used to design, develop, and implement learning programs. Although more than 40 versions of this process exist, the core of each is the same and is known as ADDIE, for analysis, design, development, implementation, and evaluation,

Analysis. To identify the desired outcomes, the current performance, and the reason that the gap between current and desired performance exists. Analysis also identifies the intended learners, as well as the

conditions that affect the design, development, and delivery of the course, such as a tight deadline and a preference for learning in a particular format. The products of the analysis process are a set of behavioral objectives, which define the learning outcomes, and a test or similar assessment, which can be used to determine the extent to which learners have mastered those objectives.

Design. To turn the requirements into a learning program. During design, the educational technologist determines the medium of instruction—such as classroom or computer-based tutorial—and the format of the course. The educational technologist also determines the learning strategy to apply—that is, the approach to presenting and reinforcing the learning content, such as a mastery or discovery approach to learning. In many organizations, educational technologists also prepare storyboards (initial drafts) of learning materials at this time.

Development. To convert the design intentions into a working learning program. The actual activities vary, depending on the type of course, but usually include preparing several drafts of the content and obtaining reviews by subject-matter experts and editors and other educational technologists, and piloting tests (i.e., trial uses of the content) with intended learners.

Implementation. To make the learning program available to its intended learners. The actual activities vary, but they usually include announcement of the availability of the program, registration, and offering of the learning program. Implementation also encompasses the activities involved in operating a learning program, such as setting up a classroom or providing technical support for computers on which tutorials are taken.

Evaluation. To determine the extent to which the learning program achieved its objectives.

Although some refer to ADDIE as a model, it is neither descriptive nor predictive of actual practice. Several empirical studies suggest, instead, that although ADDIE is an ideal process, practicing professionals do not follow it. Rather, ADDIE is prescriptive of ideal practice in the field.

Guiding each phase of ADDIE are additional processes, theories, and methods. For example, guiding the development of objectives are approaches popularized by Bob Mager in the 1960s. There are a number of approaches that guide design. Some pertain to the use of—and choice of—media, best characterized by

the debate between Richard Clark and Robert Kozma on the role of media in instruction. Some approaches focus on appropriate strategies for designing instruction. Among the most popular (but certainly not an exhaustive list) are Robert Gagne's nine events of instruction; John Keller's attention, relevance, confidence, and satisfaction (ARCS) model; and problem-based learning (D. H. Jonassen). Guiding the development of learning programs are such approaches as advance organizers, theories of document and information design, and even the appropriate use of audio and visual cues. Different approaches guide evaluation, depending on the level of education. Guiding most of them is the belief that assessment should focus on the extent to which learners can accomplish the learning objectives (known as *criterion-referenced testing*). Although high-stakes testing—that is, standardized tests to assess the performance at a particular grade level—is the type of assessment best known in primary and secondary education, using portfolios to help both learners and teachers evaluate learning is gaining much interest among educational technologists. In terms of evaluating training, Donald Kirkpatrick's four-level approach is the most dominant. It evaluates satisfaction, learning, transfer of learning to on-the-job behavior, and the impact of the learning on the organization.

In addition, some educational technologists are guided in their work by the principles of human performance technology (HPT). HPT frames most issues addressed by its practitioners as performance problems. Such problems might result from a lack of knowledge and skills and can be solved by learning programs. But performance problems might also emerge from a lack of resources (e.g., receiving training on a new software program but not having access to that program) or motivation (e.g., fearing the loss of a job resulting from new technology). Learning programs will not solve problems resulting from a lack of resources or motivation; these problems require different types of interventions. HPT emerges from the workplace. Although its advocates claim that HPT applies to all of the environments that educational technologists address, the overwhelming body of evidence is focused on the workplace.

Research and Theory

Research in educational technology has four key streams. The first stream of research focuses on the *design* of instruction. Early research tended to focus on

the design of individual lessons and courses. Some studies focused on validating a particular design strategy. For example, studies in the 1950s and 1960s focused on applications of programmed instruction, a type of instruction that breaks learning down to its smallest tasks and involves teaching a topic one micro task at a time. Other studies compared instruction in different media, such as online versus classroom instruction. The dominant research methods used for both types of studies was experimental (either control group or quasi-experimental). In many cases, researchers present experience reports, that is, reports and some research results based on their own classroom experience. More recently, research in this area has focused on learning sciences, which, as defined by the International Society on Learning Sciences, uses "empirical investigation of learning as it exists in real-world settings and how learning may be facilitated both with and without technology." Studies explore issues of learning, teaching, and design and often employ qualitative research techniques.

The second stream of research is similar to the first but focuses on *applications of hardware and software technology* to learning. In the earliest days of the field, the research focused on the use of film and audio recordings for learning. As television came into wider use, research focused on its use. In fact, the use of television for learning gave a boost to the field, because many governments wanted to use television in teaching at all levels. Since the 1980s, most of the research has focused almost exclusively on uses of computer technology in learning. Some of the research attempts to provide proof-of-concept for specific technologies in well-defined learning contexts, such as uses of intelligent tutoring in mathematics and classroom response monitoring systems (in which students are provided with a key pad to type in responses to multiple-choice and similar questions) in large classes. Some of the research explores ways to use technologies, such as some of the recent research on mobile learning (learning using personal digital assistants, like PalmPilots) and podcasting (use of audio and video recordings broadcast on MP3 players like an iPod). Some of the research focuses on the technology used to manage learning, such as LMSs, which are widely used in the workplace to help workers enroll in and take courses, and CMSs, which are widely used in universities to help extend the classroom experience online by providing a place where instructors can distribute syllabi, assignments, and readings, as well as hold ongoing discussions with learners. This research often takes the form of experimental and quasi-experimental studies, but similar to research on the design of instruction, it increasingly incorporates qualitative techniques.

The third stream of research focuses on *resources* that complement the learning process. Often, these studies explore phenomena that are both a type of learning program and a type of software. For example, according to David Wiley, one area of great interest in the first half of the 2000 decade is reusable learning objects, which are materials designed for learning in one context but available for use in others. Also of great interest are portfolios, especially electronic ones, which, as mentioned earlier, are used for evaluation of learning.

The last stream of research focuses on the practice of *educational technology*. Most of this research focuses on the practice of instructional design. Some studies focus on which skills instructional designers use on the job; others focus on how extensively instructional designers practice ADDIE. Most of these studies are survey-based, but some of the more extensive ones use methodologies like developing a curriculum (DACUM) and are the basis of certifications in the field. In addition, some recent studies partially or completely employ qualitative techniques to compile rich description of the environmental factors affecting the design of learning.

Regardless of the stream of research, most research in educational technology tends to have a "micro" focus, that is, a focus on individual learning situations, such as a comparison of a course taught in two different environments or the application of a particular technology to a particular learning problem, such as the design of an intelligent tutoring system for solving a particular type of mathematical problem.

The early use of the experimental technique in research on educational technology is representative of the field's roots in behaviorism. Indeed, many of the early researchers in educational technology, such as Tom Gilbert and Robert Gagne, had worked with B. F. Skinner. But the field has increasingly embraced cognitivism and constructivism, as researchers become aware of the situational nature of learning and want to find stronger ways to reflect that in the research. One of the many responses to this shift is design research, which attempts to study the development of a course and use the research to inform its ongoing development.

EFFECTIVE TEACHING, CHARACTERISTICS OF

Over the past several decades, a revolution has occurred in the definitions of "good" teaching. Researchers have found that defining good teachers by community ideals, personality characteristics, number of credit hours earned, or college grade point average proved disappointing, as these variables showed little relationship to what teachers actually do in the classroom. This directed researchers to study the impact of specific teacher activities on the specific cognitive and affective behaviors of their students. The term *good teaching* changed to *effective teaching*, and the research focus shifted from studying teachers exclusively to studying teachers *and* their effects on students. This new approach to studying classroom behavior has made the teacher–student relationship in the classroom the focus of modern definitions of effective teaching.

Linking Teacher Behavior With Student Performance

During this new era of research in classrooms, researchers developed methods of studying the classroom interaction patterns of teachers and students. Their goal was to discover which patterns of teacher behavior promoted desirable student outcomes. With a rich variety of classroom observation instruments, a picture of classroom activity could be captured within and across research studies and could be related to various measures of school achievement, such as better scores on classroom and standardized tests, an increase in the incidence of successful problem solving, and improved learning skills.

It was in this manner that consistent patterns of effective teaching began to emerge in studies conducted by different researchers. As in all research, some studies provided contradictory results or found no relationships among certain types of classroom interactions and student outcomes. But many studies found patterns of teacher–student interaction that consistently produced desirable student outcomes. The following are some of the most important characteristics of effective teaching to emerge from this research.

Key Behaviors Contributing to Effective Teaching

From this research approximately 10 teacher behaviors have shown promising relationships to desirable student performance, primarily as measured by classroom assessments and standardized tests. Five of these behaviors have been consistently supported by research studies over the past three decades. Another five have had some support from the research findings and appear logically related to effective teaching. The first five are key behaviors, because they are considered essential for effective teaching. The second five are helping behaviors that can be used in combinations to implement the key behaviors. The five key behaviors for effective teaching are (1) lesson clarity, (2) instructional variety, (3) teacher task, (4) student engagement in the learning process, and (5) student success rate.

Lesson Clarity

Lesson clarity refers to how clear a teacher's presentation is to the class, as indicated in the following examples:

More Effective Teachers

- Make their points clear to learners who may be at different levels of understanding
- Explain concepts in ways that help students follow along in a logical step-by-step order
- Have an oral delivery that is direct, audible to all students, and free of distracting mannerisms

Less Effective Teachers

- Use vague, ambiguous, or indefinite language
- Use overly complicated sentences that convey more than a single thought at a time

- Give directions that often result in student requests for clarification

One of the findings from research on lesson clarity is that teachers vary considerably on this behavior. Not all teachers communicate clearly and directly to their students without wandering, speaking above students' levels of comprehension, or using speech patterns that impair their presentation's clarity. A teacher with a high degree of clarity spends less time going over material and has more questions answered correctly the first time through the content, allowing more time for instruction.

Clarity is a complex behavior because it is related to many others, such as a teacher's organization of the content, lesson familiarity, and delivery strategies (e.g., whether a discussion, recitation, question-and-answer, or small-group format is used). Nevertheless, research shows that both the cognitive clarity and oral clarity of presentations vary substantially among teachers. This, in turn, produces differences in student achievement.

Instructional Variety

Instructional variety refers to a teacher's variability or flexibility of delivery during the presentation of a lesson. One of the most effective ways of creating variety during instruction is to ask questions. Many different types of questions can be integrated into the pacing and sequencing of a lesson to create meaningful variation. Therefore, the effective teacher needs to know the art of asking questions and how to discriminate among different question formats—fact questions, process questions, convergent questions, and divergent questions.

Another aspect of variety in teaching is perhaps the most obvious: the use of learning materials, equipment, displays, and space in the classroom. The physical texture and visual variety of the classroom contributes to instructional variety. This, in turn, promotes student engagement in the learning process and student achievement on end-of-unit tests. For example, some studies found the amount of disruptive behavior to be less in classrooms that had more varied activities and materials. Others have shown variety to be related to student attention.

Teacher Task Orientation

Teacher task orientation is a key behavior that refers to how much classroom time the teacher devotes to the task of teaching an academic subject. The more time allocated to the task of teaching a specific topic, the greater the opportunity students have to learn.

Some task-related decisions that a teacher must make are

1. How much time do I spend planning for teaching and getting my students ready to learn?

2. How much time do I spend presenting, asking questions, and encouraging students to inquire or think independently?

3. How much time do I spend assessing my learners' performance?

These questions pertain to how much material is presented, learned, and assessed, as opposed to how much time is delegated to procedural matters (e.g., taking attendance, distributing handouts, collecting homework, checking for materials). All teachers need to prepare their students to learn and want them to enjoy learning. However, most research studies agree that student performance is higher in classrooms with teachers who spend the maximum amount of time available teaching subject-specific content as opposed to devoting large amounts of time to the process and materials needed to acquire that content. It follows that classrooms in which teacher–student interactions focus more on subject-matter content that allows their students the maximum opportunity to learn and to practice what was taught are more likely to have higher rates of achievement. But, these classrooms also are those in which a dynamic relationship between teacher and learner provides the energy that motivates and challenges the learner to reach increasingly higher levels of understanding.

Student Engagement in the Learning Process

Student engagement in the learning process—or *engaged learning time*—is a key behavior that refers to the amount of time students devote to learning in a classroom. Student engagement is related to, but different from, a teacher's task orientation. Distinct from a teacher's task orientation—or the amount of time devoted to teaching a topic—is the time students are actively engaged in learning the material being taught. This has been called their *engagement rate*, or the percentage of time devoted to learning when students are actually on task, engaged with the instructional

materials, and benefiting from the activities being presented. Even though a teacher may be task oriented and providing maximum content coverage, some students may be disengaged. This means they are not actively thinking about, working with, or using what is being presented.

Such disengagement can involve an emotional or mental detachment from the lesson that may or may not be obvious. When students jump out of their seats, talk, read a magazine, or leave for the restroom, they obviously are not engaged in instruction. Students also can be disengaged in far more subtle ways, such as looking attentive while their thoughts are many miles away. An unpleasant fact of life is that a portion of every class may be off task at any one time, distracted for personal reasons and often amplified by an impending lunch period, a Friday afternoon, or day before a holiday. Correcting this type of disengagement may be much more difficult, requiring changes in the structure of the task itself and the cognitive demands placed on the learner. Researchers have contributed useful suggestions for increasing learning time and, more importantly, student engagement during learning. Their work has provided the following suggestions for teachers to promote student engagement:

1. Set rules that let pupils attend to their personal needs and work routines without obtaining permission each time.

2. Move around the room to monitor pupils' seatwork and to communicate an awareness of student progress.

3. Ensure that independent assignments are interesting, worthwhile, and easy enough to be completed by each pupil without teacher direction.

4. Minimize time-consuming activities, such as giving directions and organizing the class for instruction, by writing the daily schedule on the board. This will ensure that pupils know where to go and what to do.

5. Make abundant use of resources and activities that are at, or slightly above, a student's current level of understanding.

6. Avoid timing errors. Act promptly to prevent misbehaviors from occurring or increasing in severity so they do not influence others in the class.

Student Success Rate

A fifth key effective teaching behavior is student success rate. *Student success rate* refers to the rate at which students understand and correctly complete exercises and assignments.

A crucial aspect of the previously cited research on task orientation and student engagement is the level of difficulty of the material that was presented. In these studies, level of difficulty was measured by the rate at which students understood and correctly answered questions on tests, exercises, and assignments. Three levels of difficulty are

1. *High success*—the student understands the subject matter taught and makes only occasional careless errors;

2. *Moderate success*—the student has partial understanding but makes some substantive errors; and

3. *Low success*—the student has little or no understanding of the subject matter.

Not surprisingly, researchers have found that student engagement, that is, the time the learner is actively engaged with, thinking about, and working with the content being taught, is closely related to student success rate. Instruction that produces a moderate-to-high success rate results in increased performance, because more content is covered at the learner's current level of understanding.

The average student in a typical classroom spends about half of the time working on tasks that provide the opportunity for high success. But researchers have found that students who spend more than the average time in high-success activities have higher achievement, better retention, and more positive attitudes toward school. These findings have led to the suggestion that students should spend about 60% to 80% of their time on tasks that allow almost complete understanding of the material being taught with only occasional errors.

Summary of Five Key Behaviors

All five key behaviors—lesson clarity, instructional variety, teacher task orientation, student engagement, and success rate—are essential for effective teaching. Classroom researchers are studying other effective teaching behaviors and attaining a more thorough understanding of those already described. In other words, there can be no simple answer to the question, "What is an effective teacher?" Many activities must be orchestrated into patterns of behavior for teaching to be effective. The identification of only five

behaviors makes teaching appear deceptively simple. However, as the following section reveals, success in implementing these five key behaviors in the classroom will be assisted by other, helping behaviors. However, for the first time, research has provided a foundation for better definitions of effective teaching and for the training of teachers. Whereas these five behaviors constitute the skeleton of the effective teacher, there remains the heart, mind, and body to complete this picture of an effective teacher.

Helping Behaviors Related to Effective Teaching

To fill out the picture of an effective teacher, there are other behaviors that aid the teacher in performing the five key behaviors. These behaviors can be thought of as helping behaviors for performing the five key behaviors.

Research findings for helping behaviors, although promising, are not as strong and consistent as those that identified the five key behaviors. The research has not identified explicitly how these behaviors should be used. This is why helping behaviors need to be employed in the context of other behaviors to be effective, making them catalysts working in harmony with the five key behaviors rather than agents unto themselves. Among these helping behaviors are (a) using student ideas and contributions, (b) structuring, (c) questioning, (d) probing, and (e) teacher affect and the teacher–learner relationship.

Using Student Ideas and Contributions

Using student ideas and contributions includes acknowledging, modifying, applying, comparing, and summarizing student responses to promote the goals of a lesson and to encourage student participation. Note how any one of these activities could be used in achieving one or more of the five key behaviors:

- *Acknowledging:* Taking a student's correct response and repeating it to the class (to increase lesson clarity)
- *Modifying:* Using a student's idea by rephrasing it or conceptualizing it in the teacher's words or another student's words (to create instructional variety)
- *Applying:* Using a student's idea to teach an inference or take the next step in a logical analysis of a problem (to increase success rate)

- *Comparing:* Taking a student's idea and drawing a relationship between it and ideas expressed earlier by the student or another student (to encourage engagement in the learning process)
- *Summarizing:* Using what was said by a student or group of students as a recapitulation or review of concepts taught (to enhance task orientation)

More recently, the use of student ideas and contributions has been extended to reasoning, problem solving, and independent thinking. This has been achieved through teacher-mediated dialogue that helps learners construct or restructure what is being learned using their own ideas, experiences, and thought patterns. Teacher-mediated dialogue asks the learner not just to respond with a correct answer but also to internalize the meaning of what was learned by elaborating, extending, and commenting on it using the learner's own unique thoughts and experiences. In this manner, learners are encouraged to communicate the processes by which they are learning, thereby helping them to construct their own meanings and understandings of the content; this is called *constructivist teaching.*

Use of student ideas and contributions also can increase a student's engagement in the learning process. Thus, it has become a frequently used catalyst for helping achieve that key behavior. Research indicates that student ideas and contributions, especially when used in the context of the naturally occurring dialogue of the classroom, are more strongly and consistently related to student engagement than simply approving a student's answer with "good," "correct," or "right."

Structuring

Teacher comments made for the purpose of organizing what is to come, or summarizing what has gone before, are called structuring. Used before an instructional activity or question, structuring serves as instructional scaffolding that assists learners in bridging the gap between what they are capable of doing on their own and what they are capable of doing with help from the teacher, thereby aiding their understanding and use of the material to be taught. Used at the conclusion of an instructional activity or question, structuring reinforces learned content and places it in proper relation to other content already taught. Both forms of structuring are related to student achievement and are effective catalysts for performing the five key behaviors.

One method of structuring is to signal that a shift in direction or content is about to occur. A clear

signal alerts students to the impending change. Signals such as "Now that we have studied how the pipefish change their color and movements, we will learn . . ." help students switch gears and provide a perspective that makes new content more meaningful.

Another type of structuring uses emphasis. This method of structuring, called an *advance organizer*, helps the student to organize what is to follow. In this instance, students are asked to consider questions that might be raised and to know that generalizations beyond the concepts discussed will be expected. Phrases such as "Now this is important," "We will return to this point later," and "Remember this" are called *verbal markers* and can be used to emphasize important points.

In addition to verbal markers and advance organizers, the effective teacher organizes a lesson into an activity structure. An *activity structure* is a set of related tasks that increase in cognitive complexity and that, to some degree, may be placed under the control of the learner. Activity structures can be built in many ways (e.g., cooperatively, competitively, independently) to vary the demands they make on the learner and to give tempo and momentum to a lesson. For the effective teacher, they are an important means for engaging students in the learning process and moving them from simple recall of facts to higher response levels that require reasoning, critical thinking, and problem-solving behavior.

Questioning

Questioning is another important helping behavior. Few other topics have been researched as much as the teacher's use of questions. One of the most important outcomes of research on questioning has been the distinction between content questions and process questions.

Content questions. Teachers pose content questions to encourage the student to respond directly to the content taught. An example is when a teacher asks a question to see if students can recall and understand specific material. The correct answer is known well in advance by the teacher. It also has been conveyed directly in class, in the text, or both. Few, if any, interpretations or alternative meanings of the question are possible. Researchers have used various terms to describe content questions, such as direct, lower-order, convergent, closed, and fact questions.

Some estimates have suggested that up to 80% of the questions teachers ask refer directly to specific content and have readily discernible and unambiguous answers. Perhaps even more important is the fact that approximately the same percentage of teacher-made test items and behavioral objectives are written at the level of recall, knowledge, or fact. Therefore, test items, behavioral objectives, and most instruction seem to emphasize readily known facts as they are presented in curriculum guides, workbooks, and texts, leaving much less time for higher-order thinking, such as problem solving, decision making, and valuing. For the effective teacher, content questions are rarely ends in themselves but rather a means of engaging students in the learning process by getting them to act on, work through, or think about the material presented, leading to higher thought processes.

Process questions. To problem-solve, to guide, to arouse curiosity, to encourage creativity, to analyze, to synthesize, and to judge also are goals of instruction that should be reflected by questioning strategies. For these goals, content is not an end itself but a means of achieving higher-order goals. Researchers have used various terms to describe process questions, such as indirect, higher-order, divergent, open, and concept questions.

Process questions encourage thinking and problem solving by requiring the learner to use personal sources of knowledge to actively construct her or his own interpretations and meanings rather than acquiring understanding by giving back knowledge already organized in the form in which it was told. Process questions also help emphasize the learner's direct experience and the dialogue of the classroom as instructional tools while de-emphasizing lecturing and telling.

Probing

Another important helping behavior is probing, which refers to teacher statements that often follow questions that encourage students to elaborate on an answer, either their own or another student's. Probing may take the form of a general question or can include other expressions that elicit clarification of an answer, solicit additional information about a response, or redirect a student's response in a more fruitful direction. Probing often is used to shift a discussion to some higher thought level. Generally, student achievement is highest when the eliciting, soliciting, and (if necessary) redirecting occur in cycles. This systematically leads the discussion to a higher

level of complexity, as when interrelationships, generalizations, and problem solutions are being sought.

Teacher Affect and the Teacher–Learner Relationship

Anyone who has ever been in a classroom where the teacher's presentation was lifeless, static, and without vocal variety can appreciate the commonsense value of the affective side of teaching. However, unlike the behaviors discussed previously, affect cannot be easily captured in transcripts of teaching or by classroom interaction instruments. Consequently, narrowly focused research instruments often miss a teacher's affective nature, which emerges from a more holistic view of the classroom. This affective nature is the foundation from which effective teachers build a warm and nurturing relationship with their learners.

What the instruments miss, the students see clearly. Students are good perceivers of the emotions and intentions underlying a teacher's actions, and they often respond accordingly. A teacher who is excited about the subject being taught and shows it by facial expression, voice inflection, gesture, and movement, communicating respect and caring for the learner, is more likely to hold the attention of students and motivate them to higher levels of achievement than is a teacher who does not exhibit these behaviors. As a result, students will be more willing to actively engage themselves in the learning process.

Research has indicated that students take their cues from these affective signs and lower or heighten their engagement with the lesson accordingly. Enthusiasm is an important aspect of a teacher's affect in that it represents the teacher's vigor, power, involvement, excitement, and interest during a classroom presentation and his or her willingness to share this emotion with learners, who will want to respond in kind. Enthusiasm is contagious and can be displayed to students in many ways, the most common being vocal inflection, gesture, eye contact, and animation, but most importantly, how the teacher coordinates these signs to communicate that she or he cares about and respects the experiences, knowledge, and understandings students bring to the classroom. A teacher's enthusiasm has been found to be important in promoting student engagement in the learning process and achievement.

As research has turned from studying the individual characteristics of teachers to their interaction patterns with students, key and helping behaviors have been identified that are related to desirable outcomes in learners as measured by classroom and standardized tests of achievement, student projects, and performance assessments. Although not the only behaviors that define effective teaching, these key and helping behaviors provide a foundation for identifying, orchestrating, and teaching effective patterns of teacher–student interaction that result in desirable learner outcomes.

EGOCENTRISM

A child playing hide-and-seek runs to the corner of the room and covers her eyes with a pillow while her father counts to 10, believing that if she cannot see her father, then her father cannot see her. A thirsty grocery shopper spends more money than usual on bottled water and decides not to buy the salty pretzels that are on his shopping list. Political conservatives responding to an Internet poll estimate that there are more like-minded conservatives in the population than political liberals. All of these people are reasoning egocentrically. That is, they are all reasoning about the world from their own current perspectives. In the first place, people process incoming information from their own perspective. Then, they extrapolate in two ways: temporally, extending present knowledge to the past and future; and socially, extending self knowledge to others. Education involves acquiring knowledge and communicating that knowledge to others, and egocentric bias in judgment is therefore a central—but easily overlooked—issue for educators.

History

Jean Piaget is credited with the classic demonstration of egocentric reasoning in children. In one version of his experiments, children viewed a three-dimensional mountain scene that included a house that was visible from their perspective but occluded from the imaginary perspective of a stuffed bear on the other side of the scene. The children indicated that the house could also be seen from the bear's perspective, leading Piaget to conclude that children of a certain age are unable to recognize that other beings can have differing points of view. Subsequent experiments revealed potential methodological flaws in the mountain task, but improved paradigms led researchers to draw essentially the same conclusions.

Since Piaget's demonstrations, research on egocentrism has advanced in various ways. First, egocentric biases have been widely demonstrated in adults. Like children, adults readily activate egocentric knowledge when rendering judgments, but unlike children, adults learn to correct egocentric knowledge to accommodate another person's perspective. Such corrective procedures require time, mental effort, and awareness of the need to correct. Insufficient correction is a common cause of egocentric biases in judgments among adults. Second, research on egocentric biases has expanded beyond visual perspective to incorporate perspectives based on knowledge, experience, culture, attitudes, and mood.

Consequences of Egocentrism

Egocentric reasoning can occur in at least three stages of processing and can, in turn, have consequences for both acquiring and communicating knowledge.

First, people must make sense of their environment by forming representations based on their perceptions. With visual information, for example, people are generally good at forming three-dimensional representations, based on their own singular perspectives, and inferring others' perspectives from this. Consequences may emerge, however, when they neglect to consider others' perspectives simultaneously. This can be illustrated by the presenter who repeatedly points at his own computer monitor, visible only to him, rather than gesturing toward the projection of this image, which is visible to the entire audience.

Second, people understand the past and the future according to their current perspectives. For example, people often use their current knowledge when judging the past. This leads to the logic referenced by aphorisms such as "hindsight is 20/20." When judging past decisions made under uncertainty, people will often rely on the outcome without appreciating that the outcome could not have been known at the time of the decision.

Finally, people think about others using their own perspective. This leads people to exaggerate the extent to which others share their beliefs, knowledge, and opinions. It also causes communication difficulties when speakers mistakenly assume that a listener shares one's knowledge when, in fact, they do not.

Importance for Education

Given the interpersonal nature of education, educators are at particular risk of many of the biases associated with the egocentric perception of other people. At least three potential difficulties can be identified, including motivating students, preparing lessons, and delivering information.

The tendency to exaggerate the extent to which others share one's beliefs and values, what psychologists call *the false consensus effect*, can make it difficult for educators to understand what will motivate their students. A teacher who imputes his own

preferences and values to students may be trying to motivate them with the wrong incentives.

An inherent difficulty for educators, who know the material they are trying to present, is to get beyond their own perspective to appreciate the perspective of students who do not know the material. Insufficient correction can cause teachers to overestimate how easy it is for students to learn the material and to overestimate the extent to which information has been clearly communicated—a problem psychologists call the "curse of knowledge." A math instructor writing a proof on the board might skip a number of steps because she assumes knowledge of algebra beyond the students' understanding. This can lead to confused students and a frustrated instructor.

Finally, effective communication requires instructors to be precise in language and clear in intentions to avoid ambiguities in the first place and to engage in perspective taking to resolve ambiguities that do arise. Psychologists have not yet uncovered a communication panacea, but a general awareness of potential pitfalls should be a valuable step toward more effective communication.

Given that people necessarily reason about the world from their own perspective, it is difficult to overcome egocentrism. A primary challenge for those in educational practice and research is to recognize the implications of this processing orientation, to diagnose it when it occurs, and to implement practices that help to overcome or circumvent negative consequences.

EMOTIONAL DEVELOPMENT

Emotional development refers to the process of learning to effectively express, regulate, and cope with one's emotions over time. Emotional development has significant implications for children's current and future functioning. Children who successfully navigate their emotional world are more likely to also be successful in their interpersonal relationships, academic and later employment endeavors, and in obtaining personal happiness and good adjustment. Children who encounter problems with their emotional development, on the other hand, are significantly more likely to have interpersonal difficulties, academic and later employment problems, and mental health or adjustment problems. This entry will first describe the important elements of emotional development: emotion reactivity, emotion regulation, emotionality, and emotional understanding. Next, an overview of the main influences on emotional development will be presented, including the child's own characteristics, interactions with parents, and exposure to broader family interactions. Finally, a discussion of how early emotional development is linked to future adjustment will follow.

Elements of Emotional Development

Emotional Reactivity and Expression

*Emotional reactivit*y refers to an individual's response to a stimulus change, or an alteration in the environment, which is reflected in physiological changes in the individual and is observed in the excitability or arousability of response systems, in terms of temporal features (e.g., how quickly the behaviors appear following the stimulus, how rapidly they escalate, how long they last, and how quickly or slowly they go away) and intensity features (e.g., how strongly the behaviors are expressed, how sensitive they are to stimuli). High emotional reactivity would be reflected in a child who begins crying and yelling vigorously at the first hint of a disagreement occurring between his or her parents, gets overaroused quickly, and remains so for an hour after the disagreement.

Early in infancy, basic emotions such as anger, sadness, and happiness begin to emerge. As children leave the toddler phase and enter preschool and grade school age periods, their emotional expression becomes more context dependent. For example, anger and happiness are expressed more than sadness and distress in peer settings. Furthermore, their emotional expressions become more complex over time, and they may begin to show blends of various emotions

and other secondary emotions, such as pride, shame, embarrassment, and guilt. These later-developing emotions reflect more self-consciousness and awareness and develop, not coincidentally, at the same time that children are beginning to have a sense of self and to be able to discriminate, compare, and appraise the self in relation to others.

Emotional Regulation

The second basic process involved in emotional development is *emotional regulation*, which is defined as the ability to modulate, control, or reduce the intensive and temporal features of an emotion. Regulation can occur at the neurophysiological, hormonal, attentional, and behavioral levels. Behaviorally, it is observed through approach or avoidance and inhibition responses. It is reflected in the ability to effectively maintain, enhance, or inhibit emotions appropriately. The term *coping* is sometimes used interchangeably with emotion regulation, as effective coping is inseparable from effective emotion regulation and vice versa.

As infants and toddlers, children require parental help in regulating their emotions, but as they grow older, they begin to develop their own strategies for regulation. Regulation strategies that children typically use, in order from most adaptive to least adaptive are problem solving (attempting to change the situation), support seeking from caregivers or peers (either for seeking solace or help), distancing-avoidance or distraction, self-calming behaviors (e.g., taking deep breaths), internalizing (e.g., keeping feelings to self), and externalizing or antisocial behaviors (e.g., hitting others or picking a fight). Using more adaptive strategies, such as seeking solace from others or self-calming strategies, is associated with more positive outcomes for children, such as greater self-worth. Although some children attempt externalizing or antisocial behaviors as means of emotion regulation, in fact those behaviors may actually reflect a lack of managing one's emotions. Although there is not a systematic empirical literature indicating what coping strategies emerge at what age, it is known that (a) as children age, they can generate more coping alternatives, and (b) older children are better able to utilize cognitively oriented coping strategies for situations in which they have no control.

Emotionality

The third basic process involved in emotional development is *emotionality*, which refers to an individual's predisposition toward more negative versus more positive emotions and reactions. Children with more negative emotionality are prone to more feelings of sadness, anxiety, and anger, whereas children with more positive emotionality may have a greater propensity for happiness and resilience.

Emotional reactivity, emotional regulation, and emotionality all interact together and the various combinations resulting from different levels of each of the three dimensions yield numerous possibilities for outcomes. Simply being high in negative emotionality may not necessarily result in negative outcomes for a child because the child may also be quite low in emotional reactivity (i.e., the child is more prone to negative feelings, but these negative feelings are not easily invoked), or the child may also be high in emotional reactivity but be quite effective in emotion regulation (i.e., the child is prone to more negative feelings and such emotions are quickly evoked and strongly expressed, but the child is able to just as quickly regulate his or her negative emotions and return to baseline). Alternatively, a child may be high in emotional reactivity and low in emotional regulation but have more tendencies toward positive emotionality, and thus, it is not problematic that he or she reacts quickly and vigorously and is not an efficient regulator because the highly positive emotions are not problematic or requiring regulation. Thus, emotional reactivity, emotional regulation, and emotionality may interact together to serve as either protective factors against emotional problems and disorders later in life or may serve as potential risk factors. Furthermore, emotional reactivity, emotional regulation, and emotionality are each thought to be influenced by both innate characteristics of the child and by social relationships, particularly parent–child relationships early in life.

Emotional Understanding

As children develop, they become more sophisticated in their *emotional understanding*. Young children not only show an awareness of their own emotional states, but they also become more adept at evaluating and appropriately responding to others' emotions. They also become increasingly better able to describe the causes and consequences of various emotions as they grow and become increasingly knowledgeable about emotional display rules (i.e., social customs for when, how, and to whom certain emotions are appropriate to express).

Children learn a great deal about emotional understanding through their own experiences of various emotions and the concurrent discussions that ensue about their emotional states. Parents are more likely to talk about feelings with their children during times when their children are experiencing distress or anger, and children, in turn, are more likely to engage in casual conversations about feelings when they are mildly upset. These casual conversations are important sources of learning for children and result in greater levels of emotional understanding later in life.

Influences on Emotional Development

Child Characteristics: Temperament

Temperament plays a fundamental role in current conceptualizations of emotional development and is one of the main contributors to children's emotional reactivity, emotional regulation, and emotionality. Temperament is typically defined as a set of inherited personality traits that are observable from the beginning of life. It refers to the child's organized style of behavior that appears early in development, such as fussiness or fearfulness, and shapes the child's approach to his or her environment and the environment, in turn, helps further shape the child's approach. Many different researchers have put forth different opinions regarding the various constructs that constitute temperament, including a broad range of individual characteristics, such as activity, sociability, impulsivity, mood, approach-withdrawal, intensity, threshold, rhythmicity, distractibility, attention span, persistence, and adaptability. Despite these differences, the dimensions that are consistent across definitions are those pertaining to emotions. Thus, temperamental differences in infants and children may be reflected in consistent individual differences in the amount and severity of expressed negative or positive affect, fearfulness, irritability, ease of being soothed, and withdrawal from, or attraction to, novel situations across a variety of contexts.

In their key longitudinal study on temperament, Stella Chess and Alexander Thomas describe four types of temperaments that children can be classified into: easy, difficult, slow-to-warm-up, and normal/moderate. The easy category represents about 40% of children and is characterized by children who are approachable, are adaptive to the environment, possess the ability to regulate basic functions (e.g., eating, sleeping, and elimination) relatively smoothly, display predominantly positive emotionality, and settle easily into new routines. The difficult category represents about 10% of children and is characterized by children who are predominantly negative or intense in mood, not very adaptable, and arrhythmic with regard to basic functions. Children with a difficult temperament may show distress when faced with new or challenging situations and/or may have a general distress proneness or irritability, especially when limitations are placed on them. These infants cry frequently in spite of their needs being met, seem to show no regular pattern for when they eat or sleep, and are difficult to soothe. The slow-to-warm-up category represents approximately 15% of children and is characterized by fearfulness or inhibition. These children are cautious in their approach to new or challenging situations. They are more variable in regulation and adaptability and may show distress or negativity toward some situations. They fit their namesake: They are slow to warm up to situations and people, but they do eventually adapt with effort. Finally, about 35% of children fall into the normal/moderate category, which is characterized by more typical babies, that is, ones who are more moderate and fall in between categories. They are not as easy as easy babies, but not as difficult as difficult babies. They may display some negativity, but not as consistently as those with difficult temperaments. They also may display some inhibition, similar to the babies in the slow-to-warm-up category, but again not as consistently. They also have more regularity to their biorhythms than those in the slow-to-warm-up or difficult categories.

Similar to these concepts of temperament, Jerome Kagan also described two temperament categories in children that represent extremes of behavior: inhibited versus uninhibited children. Inhibited children are characterized by shy, restrained behavior and fearfulness, whereas uninhibited children are characterized by sociable, bold, and approaching behaviors. Kagan views temperament traits as being based on qualitative and innate differences.

The key question of interest with regard to emotional development is what are the links between temperament and later risk for emotional problems or psychopathology? Numerous researchers have investigated this question and have found support for moderate links. In particular, having high emotionality as an infant has been linked to anxiety, depression, and attention problems in middle school. Falling in the

inhibited category as an infant is associated with displays of shyness and withdrawal in middle childhood, more social withdrawal in adolescence, and more dependence and introversion in adulthood. Falling in the uninhibited category as an infant, on the other hand, predicts more externalizing problems and increases in aggression later in childhood. However, temperament alone is not the sole risk factor for adjustment problems later on, and not all infants who have more problematic temperaments experience emotional difficulties later in life.

Regarding developmental outcomes and the risk for psychopathology, temperament itself is not necessarily the problem. The key issue is the goodness of fit between the parents and the child's temperament. Early in life, infants are not able to regulate their own emotions, and thus, it is the parents' task to help their infant regulate negative emotions and manage the intensity of positive emotions. Parents' responses to infants' temperament can help to attenuate or accentuate temperamental extremes. For example, if a child is highly reactive and intense and needs more care but the parent is able to effectively meet the child's needs and helps soothe and regulate the infant's negative emotionality, then the parent has successfully attenuated any potential problems arising from the more difficult temperamental behaviors. On the other hand, parents who do not successfully help their child in appropriate emotion expression and regulation, or even exacerbate it due to their own negative reactions to the child's behavior, may actually increase the risk of problems for their child. Thus, how parents interact with their child's temperament and the goodness of fit between the child's temperament and the parents' reactions are what matter most.

Relational Influences

The family is clearly the most important relational influence on children's emotionality and emotional development. Traditional research has typically focused on the importance of the parent–child relationship for children's emotional functioning. Although the parent-child relationship is the most significant single category of family influence on child development, other family relationships must also be considered to obtain a more comprehensive account of family influence on children's emotional development. Emerging research over the past two decades has highlighted the importance of also considering influences of the marital relationship

on children's emotional development. Although other factors (e.g., peers, schools, culture) also undoubtedly affect children's emotional development, a consideration of these additional influences is beyond the scope of this entry.

Parent–Child Relationship

Children have some of their first experiences with internal affective states, including anger, fear, and happiness, in the context of their relationships with their parents. Furthermore, the quality and intensity of children's emotional experiences are affected by the quality of their relationships with their parents. Parents may be highly influential in young children's regulation of their own affect. For example, in parents with their own emotional difficulties, such as depression or anxiety, repeated experiences with enduring intense negative emotion can be particularly challenging for young children as they attempt to regulate their own emotions. Dimensions of parenting pertaining to emotionality (e.g., acceptance, emotional availability, sensitivity, and attachment) have been found to have substantial implications for children's emotional development. Greater acceptance and responsiveness to children's needs by parents is strongly predictive of greater sociability, self-regulation, and prosocial behavior in children, whereas parental behaviors that are more indicative of a lack of responsiveness and availability are linked with poorer outcomes in children, such as increased aggressiveness and social withdrawal.

The effects of parental behavior on children's emotional adjustment are more than a matter of just the behaviors that parents direct toward their children or even the emotional intensity of parent–child interactions or parenting. Rather, they reflect the underlying emotional quality of the relationship between parents and their children. Thus, the ways parents and children interact together are influenced by the emotional bond or attachment that has formed between the parent and child.

John Bowlby and Mary Ainsworth contend that infants' patterns of interactions with their parents develop into patterns of attachment style. In infancy and early childhood, attachment security is assessed based on Ainsworth's Strange Situation task, which consists of a sequence of brief contexts for observing the children's functioning in relation to the parent's presence, absence, and return. Children's attachment securities are classified to distinguish parent–child

relationships in terms of the child's effectiveness in deriving security from the parent in these various contexts, as well as the parent's effectiveness in providing security.

Parents who are sensitive, responsive, and consistent in meeting their infants' needs over time are more likely to have infants who develop a secure emotional attachment. Children with secure attachments are able to optimally use their parents as a secure base and as support in the context of the attachment relationship. Thus, the child demonstrates a coherent strategy for using the parent as a source of security. For example, after the parent returns from the separation, the child seeks to reconnect with the parent and is able to recover easily from any emotional distress caused by the separation, returning to happily playing. Children who have a secure attachment feel confident that their parents are there for them when they need them and are able to successfully reach their parents in times of physical, social, emotional, or other needs and be comforted.

When parents are unable to consistently meet their infants' needs, then an insecure emotional attachment is more likely to develop. Children who are not securely attached may not feel safe or comfortable seeking help from their parents because they have not successfully had their needs met in the past. Instead, they may try to hide their emotions or needs. This is typical with children with avoidant attachments. Upon the parents' return, avoidantly attached children conspicuously avoid proximity or contact with their parents, and they are not responsive to parental attempts at interaction (e.g., they may look away, turn away, and fail to proactively initiate interaction). They are more fussy and distressed during the separation and yet have more difficulty in arousal control upon reunion. Parents of avoidantly attached children are more tense, irritable, and avoidant of close physical contact and overstimulation, thus fostering less confidence in their children about the parents as reliable sources of comfort and security.

Children can also demonstrate anxious or resistant insecurity in their attachment relationships with their parents. They too are unable to effectively use their parents as a source of security in times of stress, and their strategies reflect extreme dependence. Anxious or resistant children are more clingy initially, and when insecurely attached children do attempt to seek out their parents for help, they mix anger (e.g., struggling while being held, holding their bodies rigidly, hitting, or pushing away) with excessive contact and proximity seeking. They are not comforted by their parents' attempts at consoling and have considerable difficulty settling down and returning to a more regulated state.

Bowlby and Ainsworth argue that these early attachment patterns form the basis for all other relationships that children will develop. Children use their early attachment relationships and emotional experiences with their parents as the interpretative lenses through which to view, interpret, and respond to all other relationships and interactions. In other words, they develop internal representations or schemas about how relationships work based on their relationships with their parents. Levels of parent–child attachment security provide a global sense of emotional security that influences children in many broad domains. Furthermore, children who have successfully had their emotional needs met early on are better at regulating their own emotions as they develop and thus have more success in modulating their outward expressions of emotions, such as their behavior and other communication, because they can better modulate their internal states.

Marital Relationship

The parents' marital relationship is another key factor contributing to children's emotional development. The quality of the marital relationship and the ways marital conflict are handled set the emotional climate for the family and the child. Marital conflict has both positive and negative elements however, and depending upon how it is handled, it can have either positive or negative effects on children's emotional development. Heightened levels of negative conflict can influence children directly and indirectly.

Increased conflict can directly influence children, leaving them feeling vulnerable and emotionally insecure about the stability of their family. E. Mark Cummings and Patrick Davies proposed an emotional security hypothesis, which extends the ideas from attachment theory and suggests that children can develop a sense of emotional security not just to the parent–child relationship but also to the marital relationship. From their hypothesis, children react to the meaning of conflict itself, rather than just the presence of conflict, and the more they are exposed to it, the more sensitized they become to it over time. Witnessing more negative hostile and threatening forms of conflict is particularly detrimental to children's sense of security about the marital relationship, whereas

more positive expressions including humor, support, and affection promote greater feelings of security.

Children as young as 10 months of age respond to marital conflict with distress and act markedly different to conflict than to marital harmony. Children's reactions to expressions of anger and affection in the home change over time. In middle childhood, compared with toddlerhood, children are less likely to express their emotions overtly (e.g., by yelling, crying, laughing) during angry interparental exchanges. As children develop, they are also increasingly more likely to intervene in marital conflict scenarios.

Increased marital conflict can also influence children indirectly, through negative changes in parenting. Marital conflict is associated with inconsistent child rearing and disciplinary problems, increased parental negativity, intrusive control, and low levels of parental warmth and responsiveness. Conflict in the marital relationship may translate directly into angry interactions with children or may drain parents of the energy and emotional resources necessary to effectively parent their children.

The negative effects of conflict on the parent–child relationship and children's emotional development are well established. Increases in marital conflict during infancy are predictive of insecure parent–child attachment. Children's relationships with their parents may also change because of the negative effects on their sense of trust or positive regard for their parents caused by watching them behave in mean or hostile ways toward each other.

Normal and Abnormal Emotional Development

Early generations of research on atypical emotional development documented correlations between childhood factors and later developmental outcomes. For example, describing correlations between high levels of marital conflict or negative parenting and child depression or aggression. A second generation of research is moving beyond mere correlations and seeking to understand the processes underlying children's emotional development. This is exemplified in the field of developmental psychopathology, which has underscored the importance of understanding the processes underlying normal and abnormal development.

The developmental psychopathology approach calls attention to the importance of understanding the multiplicity of individual, biological, social, familial, and other processes underlying the development of childhood problems. For example, multiple emotional, cognitive, behavioral, and physiological processes have been implicated as mediators between marital conflict and children's adjustment. The developmental psychopathology approach seeks to study children over time to provide an understanding of the developmental processes and pathways that precede and account for the development of clinical disorders in children. The developmental psychopathology approach also advocates simultaneously examining both abnormal and normal development and risk and resilience to provide a more accurate, appropriately complex and comprehensive picture of the processes that account for the risk and emergence of psychopathology in children. Psychopathology is viewed as reflecting deviations from normative patterns over time. Inherent in this concept are the notions of *multifinality*, in which the same pathways lead to different outcomes, and *equifinality*, in which more than one pathway leads to the same outcome. The approach assumes that change is possible at any point along the pathway toward abnormality or normality, although change is constrained by prior adaptation. Furthermore, emphasis is placed on the significance of context for understanding developmental patterns: What may be dysfunctional or harmful in one context may be adaptive in another.

The developmental psychopathology approach is particularly adept in understanding why some children who experience negative environmental circumstances growing up (e.g., high marital conflict, poor parenting) develop emotional difficulties, whereas others do not. For example, in examining children of depressed parents, the pertinence of such an approach is highlighted. Children of depressed parents are at heightened risk for a full range of adjustment problems, including emotional difficulties such as sadness, depression, and anxiety. However, not all children with depressed parents develop problems, and not all children develop problems at the same point in their development. This provides evidence that other environmental factors must be considered. The developmental psychopathology approach leads researchers to examine a multiplicity of factors at multiple levels to understand the processes that modify children's adjustment. For example, children may be affected by parental depression through direct exposure, altered parent–child interactions and attachment, and increased marital conflict and family discord.

Thus, it is evident there is a need for a complex flexible theoretical model that can incorporate these diverse findings and yield a viable explanation of the multiple potential pathways of development. It is not as simple as just a genetic predisposition causing emotional problems, and it is not just the presence or absence of certain factors that can lead to normal or abnormal emotional development; rather, it is the way in which these factors transpire and interact that helps account for children's adjustment at any given time.

Emotional Intelligence

Presently there is no one definition of *emotional intelligence (EI)* that is universally accepted. Psychologists have approached EI from different vantage points. Some researchers see it as the interplay of cognitive ability with emotional knowledge and regulation and have utilized self-report measures to assess the construct (e.g., Reuven Bar-On, Daniel Goleman). Other researchers have viewed EI as a distinct intelligence and have measured it in the same way as traditional IQ (e.g., John Mayer, Peter Salovey, and David Caruso). *EI* is a term that has been defined and revised by theorists and researchers in the field of psychology. A useful definition has been proposed by Mayer and Salovey, who have noted that EI is the ability to perceive accurately; appraise and express emotions; access and/or generate feelings when facilitating thought; understand emotions and emotional knowledge; and regulate feelings to promote cognitive and emotional growth.

EI is most relevant because it can be a powerful predictor of how successful a person can be in life, and it has been postulated that if children are appropriately taught, EI can be increased. In this entry, definitions of EI will be presented, ways of measuring the construct will be explained, and significant research findings will be discussed.

At Stanford University in the 1960s, a researcher made the following proposition to 4-year-old children. "I have to do an errand; if you can wait until I come back, you can have two marshmallows for a treat. If you cannot wait, you can have only one. But you can have it right now." Then the researcher left.

Following his departure, some children grabbed the marshmallow as soon as he walked out the door. Others lasted for a few minutes, but eventually the temptation was too much. Those with emotional self-control were determined to wait. These youngsters covered their eyes, or put their heads down. Others turned around in their chairs or distracted themselves by playing games or singing. Eventually the experimenter returned and gave the patient children their extra treat.

Twelve to 14 years later, these children were evaluated as teenagers. Those 4-year-olds who were able to resist temptation were now, as adolescents, viewed by their parents as more socially competent, personally effective, self-assertive, and better able to cope with the frustrations of life. They tended to be more confident, trustworthy, and dependable. They were better at taking initiative and developing projects. And, they were still better able to delay gratification to pursue their goals. In addition, those children who, at age 4, waited for the researcher to return had dramatically higher SAT scores as high school seniors. The third of children who grabbed at the marshmallow as preschoolers had an average verbal score of 524 and a quantitative score of 528. The third who waited the longest had average SAT scores of 610 (verbal) and 652

(quantitative)—a 210 difference in total score. This study, conducted by psychologist Walter Mischel, demonstrates both the short-term and future advantage of restraining emotions and delaying impulses. This is the essence of emotional self-regulation—one domain of emotional intelligence. Individuals who are better at emotional self-regulation are more primed for success—whether it is pursuing a career, building a business, or establishing relationships.

What Is Emotional Intelligence?

The term *emotional intelligence* entered the American lexicon in 1995 when Daniel Goleman published his book *Emotional Intelligence: Why It Can Matter More Than IQ.* It became a bigger buzzword, when Nancy Gibbs wrote an October 2, 1995, *Time* magazine cover story, titled "The EQ Factor." Her emphasis was that new brain research suggested that emotions, not IQ, may be the true measure of human intelligence.

Though Goleman received the most attention for his groundbreaking work, Peter Salovey and John Mayer originally used the term *emotional intelligence* in 1990 and later refined their definition in 1997. From their theoretical perspective, EI refers specifically to the cooperative combination of intelligence and emotion. The authors label their model as a four-branch ability model and divide the abilities and skills of EI into four areas: the abilities to (1) perceive emotions, (2) use emotions to facilitate thought, (3) understand emotions, and (4) manage emotions.

Branch 1 reflects the perception of emotions and involves the capacity to recognize emotions in another person's facial and postural expressions. Branch 2, facilitation, involves the capacity of emotions to assist thinking. Branch 3, the understanding of emotion, reflects the capacity to analyze emotions, appreciate their probable trends over time, and understand their outcomes. Branch 4 reflects the management of emotions, which involves the rest of personality. Emotions are managed in the context of the individual's goals, self-knowledge, and social awareness.

A second definition of EI was postulated by Goleman based on the work of Salovey. He defined EI as the capacity for recognizing one's own feelings and those of others, for motivating oneself, and for managing emotions well in oneself and in one's relationships. He sees these abilities as distinct from, but complementary to, cognitive intelligence traditionally measured by IQ tests.

He noted that these two types of intelligence—cognitive and emotional—relate to different areas of the brain. The intellect is based on the workings of the neocortex, the more evolved part of the brain. The emotional centers are in the more primitive subcortex. EI involves the interplay of the emotional centers in tandem with the intellectual centers.

In developing his definition, Goleman expanded on the work of Howard Gardner, who developed the theory of multiple intelligences. Two of these multiple intelligences were personal in nature: interpersonal intelligence (social skills) and intrapersonal intelligence (self-knowledge). In 1998, in the text *Working With Emotional Intelligence*, Goleman modified his focus in order to understand how these talents work in life. He began to label these as emotional and social competencies, which he described as learned capabilities based on emotional intelligence that results in outstanding performance at work. These include the following:

Self-awareness (knowing one's internal states, preferences, resources, and intuitions). This is self-awareness or recognizing a feeling as it happens. This is considered to be the keystone of EI. These competencies include emotional awareness, accurate self-assessment, and self-confidence.

Self-regulation (managing one's internal states, impulses, and resources). This relates to the ability to soothe oneself; that is, to shake off depression, irritation, stress, and anxiety. This is the fundamental skill of emotional self-regulation. He sees these competencies as including self-control, trustworthiness, conscientiousness, adaptability, and innovation.

Motivation (emotional tendencies to guide or facilitate reaching goals). This relates to the ability to self-motivate oneself. These competencies include achievement drive, commitment, initiative, and optimism.

Empathy (awareness of other's feelings, needs, and concerns). These competencies include understanding others, helping others develop, developing a service orientation, leveraging diversity, and maintaining political awareness.

Social skills (adeptness at inducing desirable responses in others). This requires handling emotions in relationships well and accurately reading social situations and networks; interacting smoothly; using these skills to persuade and lead, negotiate, and settle disputes for cooperation and teamwork. These competencies

include wielding influence, communicating effectively, managing conflict, providing leadership, serving as a change catalyst, building bonds, collaborating and cooperating, and creating team capabilities.

The first three—self-awareness, self-regulation, and motivation—are considered personal competencies; whereas the last two—empathy and social skills—are considered social competencies.

The third major contributor to the definition of the construct of EI is Bar-On. He refers to this construct as emotional-social intelligence (ESI). Bar-On views ESI as a cross section of interrelated emotional and social competencies, skills, and facilitators that determine how effectively one understands and expresses oneself, understands others and relates with them, and copes with daily demands. These include the following five components:

1. The ability to recognize, understand, and express emotions and feelings

2. The ability to understand how others feel and relate with them

3. The ability to manage and control emotions

4. The ability to manage change, adapt, and solve problems of a personal and interpersonal nature

5. The ability to generate positive affect and be self-motivated

How Is Emotional Intelligence Measured?

Measurement of EI has involved two major approaches, according to Gerald Matthews, Moshe Zeidner, and Richard Roberts. The first measurement approach has aligned with Mayer, Salovey, and Caruso's model of EI. To be considered a standard intelligence, Mayer, Salovey, and Caruso suggest that EI must (a) be operationalized as a mental ability, (b) meet correlational criteria that indicate it as a unitary ability that represents a new kind of performance relative to earlier measures of intelligence and personality dispositions, (c) exhibit growth with age, and (d) predict outcomes of importance.

These three authors have developed the Mayer-Salovey-Caruso Emotional Intelligence Test (MSCEIT), which meets all four criteria. This test has eight tasks: two to measure each of the four branches of EI. The MSCEIT is considered an ability test, similar

in nature to a more traditional IQ test. The examinee is asked to do a task and receives a score. For example, for Branch 1, Perceiving Emotions, in the subtest Faces, the examinee is asked to identify the emotions in faces. The authors conclude that the MSCEIT is a convenient-to-administer test that is highly reliable at the total score area and branch levels and provides a valid measure of EI.

The second measurement approach has utilized self-report measures to operationalize the models of EI presented by Goleman and Bar-On. Several measurements have been developed based on Goleman's model. One of these is the Emotional Competency Inventory, developed by Richard Boyatzis, Goleman, and Hay/McBer (now the HayGroup), which is a multirater (360-degree) instrument that provides self, manager, direct report, and peer ratings on a series of behavioral indicators of EI. It measures 20 competencies, and the rater is asked to describe him- or herself or the other person on a scale from 1 (the behavior is only slightly characteristic of the person) to 7 (the behavior is very characteristic of the person) for each item. These items are then composed into ratings for each of the competencies.

Bar-On developed a self-report measure of emotionally and socially intelligent behavior called the Emotional Quotient Inventory (EQ-i). It was the first measure on this construct published by a psychological test publisher, the first to be peer reviewed, and the most widely used measure of its kind. It contains 133 items in the form of short sentences and employs a 5-point response scale. It has five composite scales and 15 subscales. The composite scales are (1) intrapersonal, (2) interpersonal, (3) stress management, (4) adaptability, and (5) general mood.

What Are the Significant Research Findings?

Views of EI differ according to the purpose of the researchers (e.g., studying EI as a standard intelligence or as the capacity for processing and regulating emotions). Consequently, there is no consensus definition of EI. A more precise definition should be expected to emerge as researchers test the assumptions behind the different models of EI. Notably, more research is needed to delineate EI from constructs such as temperament and personality. Programmatic research by Mayer, Caruso, Salovey, and colleagues is beginning to delineate how EI converges and diverges from standard intelligence.

Research utilizing Mayer, Salovey, and Caruso's model suggests that there is a mild to medium overlap between general EI and verbal intelligence (i.e., crystallized intelligence). In contrast, results of a meta-analysis of 10 studies suggest that no more than 4% of the variance of the EQ-i can be explained by cognitive intelligence. This suggests that ESI and cognitive intelligence are not strongly related and are most likely separate constructs. In addition, there is neurological evidence suggesting that neural centers governing ESI and those regulating cognitive intelligence are located in different areas of the brain. Specifically, it has been hypothesized that the ventromedial prefrontal cortex appears to be related to basic dimensions of ESI, whereas the dorsolateral prefrontal cortex is thought to govern significant aspects of cognitive intelligence.

No differences have been revealed between males and females regarding overall ESI. However, there are a few statistically significant though small differences between the sexes for a few of the factors. Females appear to have stronger interpersonal skills than males, but males have a higher intrapersonal capacity, are better at managing emotions, and are more adaptable. The Bar-On model reveals that women are more aware of emotions, relate better interpersonally, demonstrate more empathy, and are considered more socially responsible than men. In contrast, men appear to be more self-reliant, cope better with stress, be more flexible, solve problems better, be more optimistic, and have better self-regard.

In terms of age, results from the EQ-i revealed that older groups scored significantly higher than the younger groups on most scales, and individuals in their late 40s have obtained the highest mean scores. The results seem to suggest that as a people get older, they become more socially and emotionally intelligent.

Current research has been exploring the relationships between EI, behavior, and performance (e.g., school grades, self-actualization, stress management, wellness, leadership, and occupational performance). Some noteworthy studies are highlighted here. In a path analysis study, James Parker and colleagues found that there was a .41 correlation between ESI and scholastic performance among high school students, indicating a moderate statistically significant correlation. Results seem to indicate that at least 17% of academic performance is a function of ESI in addition to cognitive intelligence.

A series of studies using large samples from the Netherlands, Israel, and North America evaluated the relationship between self-actualization and EI. Results indicated that emotional-social intelligence more so than cognitive intelligence influences one's ability to do one's best. Bar-On notes that a high IQ does not guarantee that one will actualize their potential, but a high EQ, more so than a high IQ, gives a person a better chance. This bolsters the notion that adults who eventually reach their goals are those who, as children, had the self-discipline to wait for the extra marshmallow.

Conclusion

Emotional life requires a unique set of competencies and as surely as any academic or cognitive domain can be managed with lesser or greater skill. As noted by Goleman, how adept a person is at EI is necessary to understanding why one person excels in life while another with equal cognitive skills falls short. Emotional aptitude may be conceptualized as a meta-ability that determines how well a person uses their raw intellect to navigate the rivers and shoals of life.

EMOTION AND MEMORY

People's memories of past events possess different qualitative characteristics, including overall vividness. Certain events are recalled with high clarity and a great degree of detail, whereas other events are barely remembered. Research on the effects of emotion on memory has shown that emotion can play an important role in determining such differences in recall. Positive, negative, and neutral emotions can influence whether an event or information will be richly and vividly recollected. Investigations of emotion and memory have included studies of emotion and general autobiographical memories, eyewitness testimony, flashbulb memories, and memories for traumatic events. This entry examines each of these topics.

Emotion and General Autobiographical Memories

Events that are pleasant are often processed at a deeper level and, thus, recalled more accurately and faster than events that are unpleasant. Due to more vivid imagery associated with pleasant items, memory for positive information is more accessible, durable, and frequent than is memory for negative information. Margaret Matlin proposed that this phenomenon is part of the *Pollyanna Principle.* Another aspect of the Pollyanna Principle is the *fading affect bias*, which states that unpleasant memories fade faster than pleasant memories, because the emotion associated with unpleasant events weakens in intensity more than the emotion associated with pleasant events. Thus, overall, people have the tendency to focus on positive life experiences and are motivated to view their life events as relatively pleasant.

However, the Pollyanna Principle does not seem to apply to people with depressive tendencies. Individuals who are depressed tend to focus on negative events, and as a result, unpleasant emotions do not fade more quickly than pleasant emotions. With a profound sense of hopelessness, depressed individuals' autobiographical memories are biased toward unpleasantness. These individuals often recall *mood-congruent* material; that is, they have the tendency to recall more negative than positive material because negative material is congruent with their current mood. Depression is linked to less specific retrieval of positive memories. For example, investigations of patients who have recently attempted suicide reveal that their recent autobiographical memories consist of mostly negative episodes. Furthermore, there is a delay in these patients' ability to retrieve positive memories. Individuals who are at risk for depressive moods possess automatic negative and depressive biases, while also attempting to suppress their negative tendencies to inhibit the influence of depressive biases. As a result of this conflict, they often become relatively uncertain about the meaning of ambiguous information, and their memory for such information is tainted.

Emotion and Eyewitness Testimony

Individuals who experience a history of negative or traumatic events, such as a history of sexual or physical abuse, have reduced memory specificity. As a regulating strategy, these individuals routinely retrieve autobiographical memories in a less specific way to avoid being confronted with past painful memories. This strategy may be perceived as advantageous and protective in the short term. However, as Dirk Hermans and his colleagues suggested, in the long term, a *cognitive avoidance* strategy may turn out to be

maladaptive, due to using an avoidant coping style to deal with feelings, thoughts, and problems.

Overall, about one in three people who have experienced a traumatic event report having memory difficulties retrieving details about the event, probably because they were so emotionally distracted that the normal memory encoding processes were interrupted at the time the event occurred. Researchers in the area of eyewitness testimony have indicated that similar to other types of traumatic events, witnessing a crime involves intense emotion, and such experience is capable of disrupting memory encoding and recall. The strong emotions that are elicited in a crime situation tend to draw attention to the central, salient themes of the sequence of the event, and thus, memory for the core elements is facilitated by the experience. On the other hand, peripheral details of the events are often impaired because attention is drawn to critical themes, leaving little capacity to process specific details. The phenomenon is known as the *Easterbrook hypothesis*, which states that in a traumatic condition, such as a crime situation, high emotional arousal narrows one's range of focus on the important aspects of the events, and as a result, memory for noncentral, irrelevant details is decreased or even distorted.

For example, when a bank robbery was depicted in a film in Elizabeth Loftus's research, participants who viewed a traumatic version, in which a boy was abruptly shot in the face, later recalled much less detail from the beginning of the film (e.g., the number on the boy's jersey), compared to participants who saw a nontraumatic version of the film. This finding reveals that a high degree of anxiety and emotional intensity will narrow attentional focus, drain available processing resources, and reduce memory ability. Directly related to the Easterbrook hypothesis is the *weapon focusing hypothesis.* When a weapon is used in a crime, witnesses often have clear memories of the weapon involved but hindered memories of other aspects of the crime, including central elements like the criminal's face. This phenomenon is especially applicable to people who have a high state of anxiety when seeing a weapon. A heightened sense of anxiety can trigger panic that leads to distorted memory, because different aspects of the event are not well encoded into memory.

Emotion and Flashbulb Memories

Another intriguing phenomenon in the study of emotion and memory was first referred to as *flashbulb memory* by Roger Brown and James Kulik. These investigators proposed that individuals' memory for a shocking and novel event, like the assassination of John F. Kennedy, often seems to be preserved in a photographic form that contains many circumstantial details that are resistant to forgetting. Brown and Kulik suggested that this type of memory is processed through a special brain mechanism called *Now Print*, in which the brain's flashbulb, like the camera's flashbulb, freezes the moment when the unusual event occurs, and, consequently, memory for the event is stored with piercing clarity and precise details. However, a key element that determines whether the Now Print mechanism is activated is the consequentiality of the event. A surprising event that has high personal involvement and significance is more likely to trigger a flashbulb memory. For instance, according to research findings, more African Americans than European Americans reported possessing flashbulb memories of the assassination of Martin Luther King, Jr., and Californians showed more flashbulb memories that were accurate and detailed for the 1989 earthquake in Loma Prieta (near San Francisco) than Atlanta residents who heard about the event from the news.

Other investigators have argued against Brown and Kulik's view that flashbulb memories are formed through a special brain mechanism, because research has revealed that flashbulb memories are prone to forgetting over time, just like memories for ordinary events. People's recollections of shocking, highly emotion-driven public events, such as the *Challenger* explosion, the bombing of Iraq in 1991, and the verdict of the O. J. Simpson trial, often contain distortions and can be remarkably inaccurate. As time passes, people forget or become confused about the circumstances in which they first heard about the event, and, thus, their memories for the event can show substantial degrees of decaying and fading. Nevertheless, false flashbulb memory recollections are often accompanied by high degrees of confidence by individuals. In other words, despite inaccurate recall, individuals tend to be very confident about their false memories being correct, leading to a mismatch between subjective feelings of confidence and objective accuracy of recollections.

Although flashbulb memories can fade and produce reconstructive errors over time, they are sometimes more durable and accurately remembered than many memories of ordinary events. These vivid flashbulb memories are likely to be strengthened through

repetitive discussion and rehearsal. People talk and think about the surprising event repeatedly for an extended period of time following the event, resulting in an increased memorability for the event. Overall, intense emotion and personal significance associated with an event lead to more accurate and vivid remembering of the event because these elements make an event distinctive and different from mundane occurrences.

Emotion and Memories for Traumatic Events

It is a common belief that memory for emotionally traumatic events is accurate, vivid, and detailed. Although it is often true that memory for emotionally laden traumatic events is fairly well preserved, it is not an exception to find striking errors and distortions in people's recollections of past traumatic life events. For example, it has been shown that recollections of children who have been through certain traumatic events, such as being kidnapped at gunpoint or being attacked by a sniper at school, often contain a significant number of inaccuracies, even though their memories appear to be vivid and full of details. Distortions of traumatic memories can be the result of perceptual errors due to stress experienced during the shocking episode. Seeing a mustache on the attacker's face when the attacker does not have facial hair is an example of a perceptual error caused by a high level of emotion during the event. Traumatic memories can also change over time and, thus, contain errors because of retrospective biases. Memory of an event can be later reconstructed in a way to fit a person's current emotional state after some time has passed. For example, people with a reduced level of posttraumatic stress tend to recall an original traumatic event as less threatening than their original recall of the event compared with those with a heightened level of posttraumatic stress.

Children are more vulnerable to the influence of misinformation and more apt to confuse the sources of their knowledge than are adults, resulting in mistakenly incorporating inaccurate information into their memory or failing to distinguish between an imagined and an actual event. However, inaccurate memories of traumatic events have also been demonstrated in adults who survived some brutally traumatic events like Nazi concentration camps. Thus, even extreme trauma cannot ward off possible memory erosions over time. Similarly, combat flashbacks, often reported by war veterans, can be as visually intense as if the individuals are reliving moments of the actual combat episodes. And yet, under close examination, this type of flashback is often a combination of memories of real events and constructions of imagined events. People who are easily hypnotized and have an inclination to engage in imaginative and fantasy-based activities are most likely to make claims of having flashbacks of traumatic past experiences. The authenticity and truthfulness of such flashbacks, however, have been highly questioned by researchers.

Further Research

Emotion seems to play a major role in how people's memories are initially constructed and later reconstructed during the retrieval process. High levels of emotion may enhance some aspects of memories while impairing other aspects of recollections. Investigators have used various paradigms when studying the effect of emotion on memory. Further research on this topic will continue to shed light on the role that people's emotional lives play in their autobiographical memories and on the mechanisms by which emotions exact their toll on memory.

EMPATHY

The empathic teacher and the empathic student are important topics for consideration by educational psychologists. Contemporary approaches to empathy conceive of empathy as a social interaction between any two individuals with one individual experiencing the feelings of a second individual. Although there is some degree of correspondence between the affect of the observer and the affect of the observed, the affects are not identical. The process of empathy is currently acknowledged to be contingent on both cognitive and affective factors, the particular influence varying with the age and other attributes of the individual and with the situational context. The model proposed by Norma Feshbach emphasizes the cognitive ability to discriminate affective states in others, the more mature cognitive ability to assume the perspective and role of another person, and the affective ability to experience emotions in an appropriate manner. Martin Hoffman's developmental model also has three components—cognitive, affective, and motivational—and focuses on empathic responsiveness to distress in others as the motivation for altruistic behavior.

Definitional concerns, methodological problems, and theoretical controversies have characterized this area of study. Nevertheless, the status of empathy as an important variable meriting consideration and empirical study has dramatically changed during the past 30 years. Its relevance to a number of disciplines, including neuroscience, psychology, sociology, political science, education, medicine, and the arts, has no doubt contributed to the burgeoning interest and activity in the study of empathy.

Measurement

The task of assessing empathy remains a formidable problem. The multidimensionality of the construct and the internal properties of its components leave a wide hiatus between (a) the critical role afforded to empathy in the individual's development and social behavior and (b) its data base. Assessment procedures for children's empathy vary as a function of stimulus modality (e.g., stories, audiotapes, cartoons, paper-and-pencil questions, slides, and narration), as well as response modality (e.g., reflexive crying and self-reports). More recently, measures of physiological arousal, such as heart rate and electrodermal responses, are being used to assess empathy.

Adult measures tend to be paper-and-pencil, questionnaire-type instruments. However, recent measurement developments entail the analysis of facial musculature responses to others and neuronal responses, the latter pertaining to so-called mirror neurons that match the neural reactions of another person.

Origins

The answer to the ontogenetic pattern of empathic development is unresolved. Infant responsiveness to the crying of other infants has been noted in infants as young as 2 weeks. Studies also show that infants younger than 1 year of age can respond differentially to faces depicting different affective states. In the studies by Carolyn Zahn-Waxler and Marian Radke-Yarrow, very young children exhibited "empathy-like behaviors." And while there is a close theoretical and empirical relationship between empathy and prosocial behaviors, empathy is theoretically distinct from and should not be considered as synonymous with helping, caring, sharing, or any other positive social behavior. Generally, it can be said that a cluster of empathy-related skills appear very early in an individual and become more differentiated and purposeful with age. Individuals, at any age, vary in empathic responsiveness, the source of which may be biologically/temperamentally or situationally/environmentally determined.

Antecedents of Empathy

The literature relating parent attitudes and child-rearing practices to children's empathy as well as laboratory and field training studies indicates that empathy can be taught and that empathy can be learned. How parents rear their children influences the development of empathic understanding and behavior. Mothers who are responsive, nonpunitive, and nonauthoritarian and who manifest empathic and caring behaviors enhance the development of empathy. Conversely,

parent practices that are negatively related to the development of empathy include use of threats and physical punishment, inconsistency, and reliance on extrinsic rewards. The strength of these parent–child interrelationships is much greater for mothers and their daughters than for fathers with either their sons or daughters, data that are consistent with overall findings that females are modestly, but consistently, higher in empathy than males.

Functions of Empathy

Empathy appears to play an important mediating role in a wide range of cognitive, affective, and social behaviors. These may include greater social understanding, greater emotional competence, heightened compassion and caring, greater regulation of aggression and other antisocial behaviors, and greater prosocial and moral behaviors. Studies relating empathy to such prosocial behaviors as cooperation, sharing, donating, and other altruistic acts have generally yielded positive findings, especially in adults, as have studies relating empathy to reduced social prejudice.

Because of its multifaceted structure encompassing cognitive and affective dimensions, empathy is linked to other important domains of behavior, such as communication and academic achievement. There are a number of studies showing associations between empathic understanding or the training of empathic skill and academic performance; for example, the Bonner and Aspy study relating empathetic understanding and grade point averages, the Feshbach and Feshbach training studies, the Feshbach and Feshbach longitudinal study of the relationship of empathy to reading and spelling skills in elementary school-age children, and the Kohn program on "caring school communities." Empathy should be distinguished from emotional intelligence, a concept that has received considerable attention in recent years. However, empathy is proposed to be a component of emotional intelligence.

Teacher Empathy

The salience of empathy to the educational process is especially reflected in the extensive literature on teacher empathy that was initially fueled by Halsey Rogers's approach to the therapeutic process and human development. For Rogers, empathy entails an understanding of the perspective and feelings of the client. The assumption underlying a focus on teacher empathy is the expectation that empathic communication by the teacher will result in students experiencing greater acceptance and in students developing more positive attitudes toward themselves and toward schooling.

The thrust of many of the teacher empathy studies has been on instructional techniques for enhancing teacher empathy. Most of the instructional programs entail complex, multimodal methods with varied effects, making it difficult to link teacher empathy to student outcomes. However, a few studies linking teacher empathy to student learning and behavior have found that teacher empathy is related to positive student outcomes.

Empathy in the Classroom

Today, there are a number of programs that directly or indirectly use empathy as an adjunct tool in teaching children. Earlier efforts with regard to empathy and education focused on enhancing empathy in teachers as a component of teacher competence by training them in human relations and social understanding. The focus of more current research is to show the relationship between teacher empathy and student behavior.

Future Research

Empathy appears to be a significant variable in human development and social interaction. Its complexity and internal representation, while challenging, do not preclude consideration and investigation. Promising research developments, such as the discovery of neural correlates, may help resolve some of the ambiguity in the study of empathy. Although more research is required, the process of empathy appears especially germane to the field of education, particularly educational psychology.

ENGLISH AS A SECOND LANGUAGE

English as a second language is English for nonnative speakers. Because it involves learning across the life span, it is sometimes considered to be a subfield of educational psychology. English for nonnative speakers is referred to by several acronyms: ESL (English as a second language), EFL (English as a foreign language), EAL (English as an additional language), and ELL (English language learning). There are also related acronyms, such as TESOL (teaching English to speakers of other languages). The history of ESL instruction and research will be covered in this entry, as will current practices and key issues in the field.

Introduction

English holds preferential status because it is studied as a second or additional language by more people than any other human language; it has become the global lingua franca—the language of commerce, science, technology, and other professional endeavors. It has been estimated that for every native speaker of English, there are four nonnative speakers who use it

as a second or other language. Braj Kachru described three principal contexts in which English is learned: the inner circle, the outer circle, and the expanding circle. In inner-circle countries, such as Britain, the United States, Australia, New Zealand, and Canada, the majority of speakers use English in all aspects of their lives. In the outer circle, in countries such as India, Pakistan, Hong Kong, and Singapore, English is important for historical reasons and, in many instances, is an official language, but it is not the mother tongue of many of the citizens. The expanding circle consists of countries where English was not important historically but where it is now widely used as an additional language; for example, Japan.

The theory and pedagogy of ESL draw on many disciplines, including linguistics, education, psychology, anthropology, and sociology. In the past several decades, an amalgam of these areas has developed as applied linguistics, a field that encompasses not only language learning and teaching, but translation, lexicography, and other applied language issues.

Communicative Competence

A central concept in ESL is *communicative competence*, a term first coined by Dell Hymes, a linguistic anthropologist. Communicative competence includes the skills and knowledge necessary to successfully convey meaning through language. Applied linguists Michael Canale and Merrill Swain developed a model of communicative competence that describes the components of language that are crucial to successful communication. These components are grammatical (linguistic), sociolinguistic, strategic, and discourse competence. *Grammatical competence* refers to the ability to manipulate language forms according to grammatical rules; a person demonstrates grammatical competence by using grammatical forms accurately, but he or she may not be able to articulate the rules (as is the case for most native speakers). *Sociolinguistic competence* is demonstrated when an individual uses language appropriately in different contexts. The status of participants, the purpose of the interaction, and local norms all affect what is considered to be appropriate; for example, one would use different language when speaking to a judge in court than one would when communicating the same message to a close friend. *Strategic competence* is the ability to use verbal and nonverbal communication strategies to rectify or avoid communication

breakdowns and to enhance communication. Several researchers have developed extensive lists of communication strategies, such as paraphrase, repetition, word coinage, clarification requests, and so forth. *Discourse competence* refers to the ability to link forms and meanings coherently in both written and spoken language. This includes using discourse markers, such as *first*, *next*, *then*, and *finally*, to help the listener follow a sequence of events, for example. Several researchers have developed elaborated versions of Canale and Swain's model, but the same skills and basic concepts are emphasized. Communicative competence is the ultimate goal of many ESL learners and teachers.

Historical Overview of Teaching English

Although the teaching and learning of second languages (L2s) has been a concern of educators for many centuries (e.g., John Amos Comenius wrote about his nouvelle méthode in the 1600s), this overview will be limited to the past 200 years. The oldest method of language teaching is grammar translation (sometimes called the classical method); this stemmed originally from the teaching of Latin in Europe but spread to other contexts. This method is still used today in some settings to teach English; in China, for example, the impact of the grammar translation method is still felt quite strongly. Grammar translation focuses on the translation of sentences and texts from the first language into the L2 and vice versa. In addition, explicit grammatical explanations are provided with examples, along with exercises that focus on each grammatical rule. Vocabulary instruction is based on the text that the students are translating; thus, vocabulary learning does not progress from simple to complex. There is no emphasis on speaking or listening, because the intent is to produce people who can read and write in the new language. An advantage of grammar translation is that it can be undertaken independently, without an instructor, or with an instructor who is not very proficient in the language to be learned. Grammar translation was favored initially by the educated classes; it was viewed not only as a method for learning to read classic works such as Shakespeare but also as a valuable mental exercise.

In 1880, François Gouin published a book outlining a new approach to language teaching called the *series method*. This method was a radical departure from grammar translation, founded on the premise that an L2 should be learned much like the first, focusing on everyday spoken language rather than literary texts. Gouin followed the language learning progress of his young nephew and developed the series method based on his observations. No translation is involved (hence, it belongs to a group of methods that are referred to as being "direct"); students are taught a series of connected sentences accompanied by appropriate actions or behaviors. For instance, to explain how to describe a girl lighting a stove, the students would learn sentences such as "She puts down the wood in front of the stove," "She crouches down in front of the stove," and "She opens the door of the stove." Another feature of the series method is the lack of grammatical explanation; students are expected to learn grammar implicitly through exposure in the series of sentences. Finally, the series method emphasized the importance of accurate pronunciation.

Around the same time that Gouin produced his method, Charles Berlitz and others introduced other direct methods to teach L2s. In the Berlitz approach, which is still in use today, students are taught in the L2 exclusively, and their lessons are carefully ordered from concrete, simple forms to increasingly more complex and abstract language. In the first lessons, students learn some nouns such as *pencil*, *pen*, *book*, *chair*, and so on—items that are in the immediate environment. They also learn a few questions and answers, such as "What is this?" and "This is a pen," to help generate additional language. As students progress, they learn more nouns, adjectives, verbs, and verb tenses. Grammatical points are introduced one at a time, in an inductive manner.

In the 1920s, there were several advocates of what is known as the reading method. In this case, students' only goal is to become proficient readers in the L2. It was argued that English learners in India, for example, would benefit more from reading than from any other linguistic skill; furthermore, reading was thought to be easier to acquire. The reading method makes use of the first language for explanations, and there is a heavy emphasis on vocabulary development. The reading method also focuses on the use of graded texts, reading strategies, and rapid reading techniques. This method was the first to introduce language instruction for a specific purpose. In some parts of the world, reading in English is still emphasized more than any other skill because university textbooks and many technical and scientific materials are often available only in English.

A major shift took place in the 1950s with the advent of the audiolingual method. This method drew on both the linguistic and psychological theories of the day: structuralism and behaviorism, respectively. Linguists used contrastive analysis, comparing the first language and English, to predict areas of difficulty for language learners; this information was then used to design lessons. A strong reliance on spoken language was a consequence of the linguistic principle that oral language is paramount and that written language is simply a by-product of speech. Behaviorist concepts of habit formation and reinforcement resulted in a heavy emphasis on repetition, mimicry, and memorization of controlled units of language. A typical audiolingual lesson consisted of a dialogue presented to the class by the instructor, using only the L2. The dialogue was repeated by the students several times in chorus, and then in smaller groups. The emphasis was on speaking accurately, both in terms of grammar and pronunciation. Students were given positive feedback for correct productions; errors were avoided by the use of intensive drill. Students were often assigned homework in the language lab where they practiced grammatical patterns. Reading and writing were secondary in importance to the development of good speaking skills. Because of its scientific reputation, as well as heavy financial support from governments and publishers, the audiolingual method became extremely influential.

As a reaction to the behaviorist underpinnings of audiolingualism, the cognitive code approach developed in the late 1960s. The main premise of this approach is the need for the learner to explicitly understand the rules of the language at all levels, rather than simply memorizing dialogues or other chunks of language. Instructors actively teach phonological and grammatical rules, and all four skills (reading, writing, listening, and speaking) are taught together.

Other alternatives to the audiolingual method were classified by H. Douglas Brown as the "designer methods" of the 1970s. These were idiosyncratic and largely atheoretical approaches to language teaching developed by charismatic professionals, most of which are not practiced extensively today. In the Silent Way, developed by Caleb Gattegno, students' exposure to vocabulary is extremely limited in the first month. Words are represented on wall charts, and each letter is color-coded to provide a visual representation of sound and spelling correspondences. Students are encouraged to rely heavily on each other rather than on the teacher, who is to remain as silent as possible. The Silent Way requires considerable training on the part of the teachers.

Another method, developed by Georgi Lozanov, is Suggestopedia, which originated in Bulgaria. In this approach, students are given a new persona. Classes are small and take place in a comfortable setting with easy chairs. The teacher is required to use Baroque music for the séance component of the lesson, during which the students are instructed to use yogic breathing in time with the music while the teacher relays the dialogue in a whisper, a dramatic voice, and in a normal reading. Lozanov claimed that the new personas taken on by the students alleviate a fear of making errors; he also stated that the vocabulary gains with Suggestopedia are far superior to those of any other method.

Like Suggestopedia, one of the aims of community counseling learning, which is based on principles of Rogerian psychology, is to reduce anxiety. The students sit in a circle while the teacher (counselor) stands behind them. When one student chooses to say something to another, he or she utters a sentence in the first language and the counselor translates it into the L2. The student then repeats the translated utterance, and the counselor moves to the recipient to translate a reply. The students then work together on a tape recording of the lesson to work out the linguistic features of the new language.

James Asher, the proponent of the total physical response (TPR) approach to language learning, maintained that physical actions reinforce the learning of vocabulary. In response to a series of the teacher's commands, students are required to act out a sequence of events (much like Gouin's series method). For instance, students may be shown a sequence of actions that mimes washing the dishes. Their instructor then encourages them to respond to commands such as "Put in the plug," "Turn on the tap," "Put soap in the water," "Turn off the tap," and so on. Asher argued that, by acting out the behaviors, students developed a physiological memory of their new language. Asher believed that the acquisition of a L2 was the same as the acquisition of the first language, and he encouraged a silent period in adults that parallels that observed in many children. Once learners feel comfortable with the commands, he claimed, they will start to speak on their own.

ESL Teaching Today

In the early 1980s, communicative language teaching (CLT) became the most popular approach to ESL in North America. At the same time, in Europe the notional-functional approach was widely implemented. Both are still widely practiced today, either in their original form or in an adaptation. The notional-functional approach broke away from a reliance on grammatical structures as the organizing principle for L2 courses and focused instead on functional uses of language, such as greetings, invitations, apologies, opinions, and notions (contexts) such as shopping for groceries.

CLT emerged out of the communicative competence framework established by Canale and Swain and Stephen Krashen's model of L2 acquisition. Krashen argued that L2 acquisition depended on exposing the learner to comprehensible input—that is, language that the learner could understand with the use of contextual clues. He suggested that the input should be at a level just slightly higher than the learner's own proficiency. For this reason, he advocated the use of TPR in the early stages of acquisition, because the meaning of the actions and accompanying language are readily apparent. Perhaps the most contentious aspect of Krashen's theory was the distinction he made between learning and acquisition. Krashen maintained that learning involved consciously putting into memory vocabulary and grammar, whereas acquisition was the subconscious "picking up" of an L2. He claimed not only that learning played a very small part in the overall development of an L2 but also that learning could not turn into acquisition. In other words, learning and acquisition were viewed as two unconnected processes, and learning simply acted as an editor of acquired spoken and written forms.

Another aspect of Krashen's theory that was widely challenged was his claim that the only requirement for mastering an L2 is that the learner is exposed to enough comprehensible input which gradually becomes increasingly complex. Michael Long challenged Krashen's claim, arguing that comprehensible input is a necessary but insufficient component of language acquisition and that interaction, which involves negotiation of meaning, is essential.

Many ESL teachers embraced CLT and designed lessons that provided comprehensible input but did not explicitly teach grammar. Borrowing from notional-functional approaches in Britain, many classroom curricula were developed around themes such as "going to the doctor" and functions such as "making an argument." Often lessons centered on vocabulary development, role playing, and group work.

Although students in CLT classrooms often became relatively fluent in English, they persisted in making grammatical errors. Eventually, applied linguists such as Swain, Richard Schmidt, and Long argued that L2 learners needed a focus on form within a communicative framework. Swain put forward the output hypothesis; she maintained that unless pushed by interlocutors, students analyze their L2 at a semantic level but pay little attention to syntactic structures. By focusing on their own output, that is, their own productions in the L2, they are pushed to become more accurate syntactically because of the feedback they receive. Similarly, Schmidt proposed the noticing hypothesis. He suggested that unless learners have certain linguistic elements brought to their attention, they will not notice them in the input; in other words, a grammatical structure that is not salient or transparent will not be acquired unless teachers instruct the students, either explicitly or by focusing their attention on that form in a task that requires its use.

Recently, some educational theorists have shifted away from viewing L2 learning as a purely psychological phenomenon and toward viewing it as a social construction. The emphasis is on language as a social practice that takes place among people as they negotiate and co-construct meanings in a range of contexts. In pedagogical situations, a sociocultural approach does not focus on language learning as an independent activity. Students are encouraged to interact, using each other as supports while creating collective and collaborative discourse relevant to their own experiences, interests, feelings, and ideas. There is also recognition that identity is inseparable from situational and cultural contexts and language. Thus, social positions and the relative power that they entail are considered to play a key role in language learning processes.

Most of the preceding discussion has focused on language classrooms, but ESL is also taught through content in K–12 settings to immigrant or aboriginal children. There is a variety of delivery methods for school-age children, including pull-out for one-on-one instruction or small group work, separate ESL classrooms, and adapted lessons of subject matter that are appropriate for both ESL and native-speaking students. Bernard Mohan and his colleagues proposed

the knowledge framework approach to adjusting the basic school curriculum to make it accessible to ESL students in mainstream classrooms, while at the same time helping them to recognize how English works. Teachers are encouraged to analyze the subject matter to be taught and the students' texts to determine which knowledge structures (classification, principles, evaluation, description, sequencing, and choice) are evident and which linguistic structures are expressed there. For example, in a science text dealing with a topic such as pollution, there are likely to be discussions of cause and effect (principles) and types of pollution (classification). Each of these knowledge structures is characterized by particular linguistic forms. Cause and effect is often represented by phrases such as *is due to, because of*, and *as a result of.* Mohan advocates the use of key visuals (e.g., time lines, flow charts, tables, diagrams) to help students see the relationships among concepts and the words that express them. Schools that have used this model have found it to be quite successful, but it is extremely time and effort intensive for individual teachers to modify their lessons along these lines.

Two other approaches that are sometimes used to teach English to K–12 learners involve dual language and bilingual programs. The former can be characterized as two-way immersion. In New Mexico, for example, there are several schools in which half the students are native English speakers and half are native Spanish speakers. The students study in both languages and develop oral and literacy skills in both. Bilingual schools are patterned after immersion schools in that subject matter is taught in the students' first language and in English, usually a half day of each language. In Edmonton, Alberta (Canada), children can choose from more than a dozen languages that are taught in conjunction with English.

There is growing concern in some communities that students in K–12 classrooms are not becoming proficient in English. One of the most vocal advocates for ESL students is Jim Cummins, who proposed that children's oral fluency can be misleading because they quickly learn basic interpersonal communication skills, but they take much longer to acquire cognitive academic linguistic proficiency. To achieve academically, students require up to 8 years of language support, but most school districts do not have the resources to provide the programs that ESL students need.

EFL

Most of the methods and approaches described previously in this entry can be found in practice somewhere in the world today in EFL settings. Because the goals of learners in these contexts are so diverse, communicative competence is not necessarily the ultimate objective. Thus, reading courses may be all that is required of students in some situations, because their content textbooks are written in English. However, there is a growing desire for oral proficiency, in some locations, that has resulted in some novel pedagogical developments. In both Korea and Spain, for example, whole English-speaking towns have been established, where native speakers of English go on a paid holiday for the express purpose of talking with Korean or Spanish EFL learners in English. Every encounter is an opportunity for a learner to have an authentic conversation with an English speaker.

Factors That Affect Ultimate Attainment of English

There are several variables that determine whether a learner can become completely proficient in English. Age of learning has long been proposed as having a major influence on ultimate attainment. It was thought that puberty was a critical period for L2 learners; however, research by James Flege and his colleagues showed that there are many individuals who started learning English much earlier than adolescence who are easily identified as L2 speakers. They have proposed that there is a sensitive period very early in life for complete language acquisition. Others have suggested that some adult learners have attained full proficiency; they argue that other factors, such as amount of exposure, motivation, quality of instruction, issues of cultural identity, and native language, have more impact on ultimate attainment than age.

Current Issues

There are several controversial issues in English teaching today, one of which has to do with the variety of English that should be taught, particularly in EFL settings. Some people believe that a standard version of English such as Received Pronunciation (the Queen's English) or standard American English is the best model for communication. Others have argued that the local variety of English should be taught, such as

Indian English in India. The students' purposes for learning English and who they intend to interact with should determine the model that they require.

Another ongoing issue has to do with ESL assessment, which is not only a thriving business but also a high-stakes enterprise for L2 learners. Organizations such as Educational Testing Services produce tests such as the TOEFL (Test of English as a Foreign Language) and the TOEIC (Test of English for International Communication). The TOEFL is used by most postsecondary institutions in North America as an admission criterion for international students. The TOEIC is often required for job promotions in non-English-speaking countries. Because the stakes are so important for test-takers, what they choose to study and what is taught are often dictated by the nature of the tests. In the past, these tests and others focused on discrete elements of English, but they now tend to integrate linguistic skills.

Another matter that concerns many instructors is the question of whether an English teacher should be a native speaker. Nonnative instructors have argued that they have a better understanding of the difficulties faced by their students; they also offer a more realistic model of what can be accomplished. However, in many EFL contexts, employers give preference to native speakers of English, even though many have little or no training. Others argue that native speaker status is immaterial and that there are two fundamental requirements of any good ESL or EFL teacher: high proficiency and high linguistic awareness in English and strong pedagogical skills.

In recent years, there has been a growing recognition that ESL and EFL instructors should be professionals and should meet standards established by national or international organizations. Furthermore, standards have also been developed for programs. There are still many contexts in which English is taught where neither the instructor nor the program has been approved or meets any set of standards, but this will likely change in the coming decades.

Episodic Memory

Episodic memory refers to a division of declarative memory responsible for storing and retrieving information about one's own personal experiences. Episodic memory is the theoretical component of the memory system that allows one to revisit and relive events that occurred within one's personal history. Once experienced, events such as one's first day of school, graduation day, and one's first kiss can each be called into consciousness and relived at a later time because of episodic memory.

Episodic memory is defined in a manner similar to another common memory system, autobiographical memory. Indeed, episodic memory and autobiographical memory are similar enough that some theorists have suggested that the two terms be treated as synonymous. However, this proposal has been met by some resistance from advocates of autobiographical memory, who point out that memory theorists who study autobiographical memory tend to focus their attention on how participants remember events of personal significance, while those interested in episodic memory display far less emphasis on memories for events of autobiographical significance. Some theorists have taken steps to further distinguish between autobiographical memory and episodic memory by listing measurable differences between the two systems. For example, one such difference would be that episodic memories are typically retained for a short period of time, whereas autobiographical memories are retained for a longer time.

Episodic Memory in Educational Psychology

Specific attempts by educational psychologists to study episodic memory have been relatively rare. This

is surprising in that there are some intuitive applications of episodic memory research that those in the education field may find potentially valuable. Although it seems plausible that more advanced knowledge of the application of episodic memory research to education domains might allow for the development of educational curricula that students are more likely to remember, little research has been performed on this idea to date. Recently, some psychologists have argued that an increased emphasis on episodic memory in educational psychology could lead to curricula specifically designed to make it more likely that students remember teaching and learning experiences. Exploration of the intersection between these two active research areas may prove to be a productive avenue for future research.

History of the Concept

In 1972, Endel Tulving proposed a distinction between episodic memory and semantic memory (the memory system responsible for storing facts and general knowledge regarding the way the world works). In his framework, however, episodic memory is not truly independent of semantic memory but rather is a subsystem that is highly dependent on semantic memory.

To help operationalize the differences between episodic memory and other forms of memory, Tulving proposed that we have two ways of accessing the events from our past: remembering and knowing. In Tulving's conceptualization, we "remember" a piece of information from the past when the information is accompanied by the conscious recall of specific details associated with original experience of the information. In contrast, we sometimes remember information from the past but have no conscious recollection of any details about how we learned the information. Tulving referred to this type of access to the past as "knowing."

Upon its introduction, the distinction between episodic memory and semantic memory was readily accepted as a useful heuristic for classifying memory tasks and procedures. However, controversy soon bloomed when it was proposed that episodic memory and semantic memory were functionally and biologically distinct systems.

Evidence for Separate Systems

Tulving and his colleagues have developed a number of lines of evidence intended to differentiate episodic memory from semantic memory. These lines of evidence range from the phenomenological, to the traditionally behavioral, to the physiological. On the phenomenological end of the evidence, Tulving points out that episodic memories have an affective tone associated with them that is missing in semantic memory. A more traditionally behavioral area where episodic memory has been theorized to dissociate from semantic memory is in how likely subjects are to lose information from the respective systems. Some have proposed that episodic memory is more vulnerable to forgetting than is semantic memory.

Physiological evidence for a distinction between episodic and semantic memory systems comes from neuropsychological case studies. The best example of these case studies comes from patient K.C. (amnesic case studies are frequently referred to by their initials in the neuropsychological literature to provide a degree of protection for their anonymity). K.C. exhibits symptoms consistent with a distinction between episodic memory and semantic memory in that his episodic memory was almost entirely destroyed in a motorcycle accident, while his semantic memory remains relatively intact. K.C cannot recall any personal experiences but is able to learn new facts. Although a handful of similar cases exist, brain damage similar to that observed in K.C. is extraordinarily rare. These cases demonstrate that it is possible to have a functional semantic memory in the absence of episodic memory.

Functional neuroimaging studies have been used to identify the physiological underpinnings of episodic memory. Distinct patterns of cortical activation associated specifically with episodic memory have been identified. Neuroimaging studies have typically found medial and left lateralized activation patterns associated with retrieval of episodic memories. In particular, the medial frontal cortex and left hippocampus tend to be active during episodic memory retrieval.

Criticisms of the Separate Systems View

Although the previously discussed evidence has been interpreted by Tulving and others as support for the idea that episodic memory is a memory system distinct from semantic memory, some have argued that this distinction is unnecessary. In keeping with the scientific value of parsimony, it has been argued that there may not be a need to hypothesize multiple

memory systems. Indeed, several of the studies cited as evidence for a distinction between semantic memory and episodic memory have been questioned by the theory's critics. For example, critics note that the hypothesized distinction between forgetting rates in episodic memory and semantic memory does not seem to be supported by the data.

Research

Since the episodic memory distinction was first proposed in 1972, hundreds of studies of episodic memory have been conducted, and episodic memory remains an active area of research today. Although memory theorists continue to debate whether episodic memory is a truly separate system from semantic memory, most agree that the concept of episodic memory has utility.

EQUILIBRATION

Developmental theorists make a distinction between developmental states and developmental mechanisms. *Developmental states* are chronologically arranged snapshots of children's skill levels at particular points in time. An example of a sequence of developmental states would be the four stages of cognitive development that were proposed by Jean Piaget in his classic theory (i.e., sensori-motor, preoperations, concrete operations, formal operations). As children enter a new stage, they acquire a new set of skills and move to a new level of performance. *Developmental mechanisms*, in contrast, are the factors that are used to explain children's progression through developmental states (i.e., why a child progresses from one state to another in a sequence). The primary developmental mechanism in Piaget's theory is called equilibration. *Equilibration* pertains to restoring the balance between two competing tendencies in the mind: assimilation and accommodation. Piaget used the notion of *assimilation* to describe the process of incorporating experiences and information into existing knowledge structures in the mind. Metaphorically, children find a "home" for this information in their existing knowledge structures. To say that a child has assimilated an idea or experience is to say that he or she understood the idea or experience. Piaget thought that mental assimilation was analogous to the biological assimilation that takes place when the human body extracts what it needs from food and incorporates the extracted nutrients into existing organs and tissues.

Sometimes an idea is so discrepant from what a child believes or knows that it cannot be assimilated. Piaget used the notion of *accommodation* to describe the process of changing the existing configuration of knowledge in the mind in order that the troublesome idea can be assimilated. In most cases, assimilation is always partial in the sense that children only assimilate that portion of an experience that is consistent with their current understanding. And unless an experience or idea is identical to previous ones, every act of assimilation usually precipitates accommodation of knowledge as well. For example, when a child encounters a new species of dog for the first time and is told that it is a dog, this information finds a home in the existing network of ideas (i.e., it is assimilated), but the network is also changed as the child's mind creates a new representation corresponding to the new subtype of dog (i.e., there is accommodation).

In his book, *Play, Dreams, and Imitation*, Piaget argued that "imitation is a continuation of accommodation, play is a continuation of assimilation, and intelligence is a harmonious combination of the two" (p. 104). This quote suggests that when one assimilates, one inserts one's own ideas into reality; when

one accommodates, one's schemes and ideas come into closer conformity with reality and tend to be fairly direct copies of it. Play and fantasy, moreover, are examples of overassimilation (i.e., putting too much of one's ideas into reality). In contrast, children engage in overaccommodation when they try to directly copy the actions of someone (without putting their own "spin" on the actions).

To illustrate assimilation and accommodation further, consider the following example. Young preschoolers who are passengers in their parents' cars often think that the moon is following them when they drive at night. The physics of the explanation of what is actually happening is too abstract for young children to comprehend, so they could not assimilate even this explanation if it were provided. Ultimately, however, their knowledge of the physical world will change enough that they may eventually understand the explanation as young adults.

Piaget argued that confronting discrepant ideas is absolutely essential for knowledge growth. If children never had experiences or heard information that contradicted the erroneous ideas that they construct by themselves, they would never develop the correct conceptions. Thus, the "readiness" idea of waiting until a child's mind matures enough to teach a topic to them is actually an implication of nativism, not Piaget's constructivism. Piaget did not believe that ideas were inborn as nativists do; rather, he believed that children build up their ideas step by step.

Moreover, Piaget argued that assimilation and accommodation work in opposition to each other. The central tendency for assimilation is to keep the existing knowledge structure the same and find a place for new information in this structure. The central tendency for accommodation, in contrast, is to change the existing knowledge structure. It is not possible to keep things the same and change them at the same time. Thus, only one or the other—assimilation or accommodation—"wins out" in a given situation. This "battle" between these processes means that change in children's misconceptions can be frustratingly slow for teachers. That is, even when a misconception is repeatedly pointed out and explained to children, they may cling to the erroneous idea for some time. Perhaps this implies that assimilation normally takes precedence over accommodation. When the battle is resolved over some idea and a balance is restored between assimilation and accommodation (i.e., equilibration has occurred), children's

understanding usually moves to a higher plane and often becomes more abstract as well. For example, for children to come to understand that dogs and people are both animals, they have to change their concept of "animal" in such a way that it is more abstract (e.g., "a living thing that can move itself" from "furry four-legged things").

Piaget argued that equilibration was particularly adaptive because the changes that are incorporated into mental structures are such that the mental system of ideas becomes capable of anticipating future problems that might arise. That is, the change not only allows a child to assimilate a particular idea that once was difficult to grasp but also helps the child grasp related ideas that he or she has not yet encountered. In this way, equilibration works in a manner analogous to how the immune system creates structures (i.e., antibodies) that can deal with problems that arise in the future (i.e., reoccurrence of a virus that was encountered before).

ERIKSON'S THEORY OF PSYCHOSOCIAL DEVELOPMENT

In one biography, Erik Erikson is referred to as an architect of identity. He was trained in psychoanalysis, and one of his main scholarly interests was

describing the nature of humankind. He engaged in personal and cultural observations in his theoretical writings about identity formation. His major contribution was the formulation of an elaborate life-span theory of identity formation based on eight life stages. Each stage is based on age-appropriate and culturally defined crises, or turning points, which demand that the individual choose between dialectic and opposing developmental outcomes. Each stage outcome provides a contribution to identity formation in the form of ego strengths.

Erik Erikson's theory of psychosocial development has been useful in helping teachers and educators to understand child development for more than 50 years. It remains a solid theoretical perspective for understanding child and adolescent development and adult learning. There is an ever-expanding body of research that demonstrates Erikson's many ideas can be empirically supported as being valid and practical.

Definitions of Identity

Identity is defined in many ways. Most often Erikson refers to *ego identity*, or the portion of personality that functions to direct, guide, and select thought and action. It is the part of personality that refers to the consistency and sameness that a person uses as a style of individuality and its meaning about the self for significant others like family members, teachers, or friends. Identity can be thought of as a form of relatively persistent character one shares with others.

In addition to ego identity, Erikson also refers to the stable and coherent, but yet evolving, character one develops with a group's ideals in the form of social identity. Social identity is most readily observed in the expectations and commitments to the values, goals, and ideals of institutions such as religion, politics, occupation, and the family. In particular, social identity is based on the ideology that is formed within a commitment to a particular institutional value. For example, an occupational identity based on the achievement motive of capitalism differs from an occupational identity based on the conformist motive of a communism ideology. Religious identities differ within Protestant, Catholic, Islamic, Hindu, Jewish, or other forms of religious social ideologies. Likewise, political identities vary among party, state, or group ideologies.

Families vary as to the values, goals, and aspirations that parents have for their children, and identification with family ideologies will vary widely within any given community. Many factors will contribute to whether youth will identify (or not) with their own family values and ideologies. Indeed, individuals strive toward psychology unity, where various domains of identity across the various institutional ideologies merge into a comfortable coherent and consistent sense of individuality. Extreme differences in values or incompatible goals or values in adopted commitments create angst or anxiety that links with self-consciousness and discomfort, leaving a person with a sense of fragmentation. A fragmented self (or incompatible elements within either an ego identity or a social identity) will lead to uncomfortable states of anxiety and a sense of inner conflict.

Eight Life Stages

The eight life stages that facilitate identity formation are set by societal expectations to accomplish specific developmental tasks. Each of these tasks, as it is successfully resolved, provides an innovative strength to both ego- and social-identity development. These stages are based on an epigenetic principle wherein the individual is driven toward, is aware of, and interacts with life dilemmas. Human growth is based on a dialectic struggle of inner (psychological) and outer (social) forces where each stage of life involves a crisis or turning point. Each of the life stages provides a critical point to increase potential for growth in identity based on an ontogenetic evolution. Healthy development is based on the assumption that every stage comes to its ascendance: A crisis is resolved and is, ideally, concluded with an effective and meaningful identity resolution. To complete a life stage, a person must synthesis (or resynthesize) early childhood identifications for novel and newly constructed identifications. Put another way, the individual must both selectively repudiate and assimilate childhood identifications with new configurations of ego identity.

Each stage of life consists of issues regarding a designated age or stage, questions and virtues, appropriate precursors, contributions to identity, and a radius of social order. Erikson begins with infancy and a crisis of trust versus mistrust. In general terms the question to be answered is "What do I have and what can I give?" The virtue is hope. In early childhood, the crisis is autonomy versus shame and doubt. The question is "What can I will freely?" and the virtue is will. Somewhat later in childhood the crisis becomes

initiative versus guilt, and the question is "What can I imagine I will be?" The virtue is purpose. For the school-age child, the crisis is industry versus inferiority, and the question is "What can I learn to make?" The virtue is competence. In adolescence, the crisis is identity versus role confusion. The question is "Who do I choose to be ideologically and occupationally?" The virtue is fidelity. In young adulthood, the question the crisis is intimacy versus isolation. The question focuses on "What I can give to another?" The virtue is love. In middle adulthood, the crisis is generativity versus stagnation. The question is "What I can give and care for?" The virtue is care. As one approaches old age, the crisis is integrity versus despair. The question is "What is the essence of my existence?" The virtue is wisdom.

The radius of social order begins with the important power of the maternal person and expands through school, community, technology, and beyond. In infancy, the contribution to identity is time perspective versus time diffusion, and the radius is the maternal person. In early childhood, the contribution to identity is self-certainty versus identity consciousness, and the radius is parental care. In childhood, the contribution is role experimentation versus negative identity, and the radius is the basic family. For the school-age child, the contribution is the anticipation of achievement, and the social radius is the neighborhood, school, and technology. In adolescence, the contribution is identity consolidation, and the social radius includes peer groups, models of leadership, and ideological perspectives of the social institutions associated with occupation, family, religion, and politics.

Importance of Psychosocial Moratorium

Each of the first five life stages provides an important precursor to identity formation, and the remaining three offer further consolidation through the virtues of love, care, and wisdom. However, Western societies, in particular, provide an extended period of time for role experimentation to explore identity options and select and make commitments to those identity fragments that will become integrated into a uniformed sense of ego identity and social identity. This period of time is called a *psychosocial moratorium*. It is a period when schools, parents, and communities allow for experimentation and offer opportunities for teenagers and sometimes even emerging adults to explore what they can do to select and prepare for an occupation, profession, or career. During this time, youth can find many teachers, parents, adults, and others ready to role model and assist in preparing them through education, mentoring, and apprenticeship experiences. Failure of youth to effectively utilize the psychosocial moratorium can result in a negative identity whereby youth identify with negative features or characteristics of society that cause the youth to appear rebellious or alienated.

Women's Identity

The most controversial aspect of Erikson's theory of identity development is his writings on gender differences. In early psychoanalytic writings based on observations during play therapy, boys were observed to use play building blocks to make towers, whereas girls made circles or walled enclosures. This led to notions of boys using outer or phallic space and girls using inner biological space in their psychology development and to the belief that girls' development was based, in large part, on their biological destiny of procreation and motherhood. Thus, identity formation for men occurs with identity formation functioning clearly as a precursor to intimacy formation. In contrast, for women, identity formation unfolds concurrently with intimacy formation. There has been ample critique of this controversial statement on gender difference; however, there is little strong empirical research evidence of a longitudinal nature to establish whether or not this hypothesis is accurate. Most of the evidence that has been presented to indicate Erikson's notion of biological destiny for women's identity formation trajectory has been of a qualitative nature and could easily be interpreted arguably as supporting or not supporting this assumption. Nonetheless, the position on biological determinism was maintained by Erikson throughout all of his lectures, writings, and interviews. In a historical period of heightened feminism, this position was unpopular and often criticized.

Identity Statuses

Theoretical perspectives are often difficult to define and measure. Only limited aspects of Erikson's theory of psychosocial development have been defined well enough to measure. The two stages most widely studied have been *identity versus role confusion* and *intimacy versus stagnation*.

James Marcia identified two dimensions from Erikson's writings that are part of the developmental process of identity formation. These dimensions include a searching or crisis process and an outcome of commitment. Using these two dimensions and crossing them at the midpoint in the middle he created four states (which he called *statuses*): no searching and no commitment, no searching and commitment, searching and no commitment, and searching and commitment. In his framework, searching, or *identity crisis*, involved active attempts to formulate or construct an identity. *Commitment* refers to the construction and formulation of a comfortable sense of identity. No searching and no commitment is called *identity diffusion.* No searching but with commitment is called *foreclosure*, a form of identity where there is a passive acceptance of identity of a previous generation or parents. Searching but no reported commitment is called *moratorium*, an individual who is in the process of actively trying to formulate a sense of self through discovery and or self-creation. Finally, evidence of past searching and current commitment is called *identity achievement*. Clinical and social science research reveals that adolescents and youth with diffused ego identity are most likely to have mental health problems, whereas their peers who are identity achieved are most likely to have the best mental health of the four types of identity status types. These findings are fully consistent with Erikson's theory of ego-identity formation.

Jacob Orlofsky and colleagues used three major criteria for assessing a person's level of intimacy as suggested by Erikson:

1. Does the person have close relationships with male and female friends?

2. Does he or she have an enduring heterosexual relationship?

3. Are the person's close relationships deep or superficial? (Depth includes openness, affection, respect, loyalty, a capacity to accept and resolve differences, and mutuality.)

Based on these criteria, five relationships, or intimacy statuses, can be identified through interview techniques. At the two extremes are the intimate and the isolated statuses. The intimacy status involves love and an enduring commitment. In the isolated status, the person is withdrawn and has no close personal associations. Between these two extremes are three other types. The preintimate status is a loving relationship but with no enduring commitment. A stereotyped status is an association with male or female friends that lacks depth and closeness. The pseudointimate status is artificial; it only seems to have depth and caring.

Wide use of the intimacy and identity statuses has revealed that individuals who are identity diffused are also intimacy isolated. In contrast, identity-achieved individuals have considerably more intimate relationships. This is again consistent with Erikson's notions of interstage linkages among identity and intimacy resolutions in the fifth and six stages of ego-identity development.

Power of Educational Institutions

Social institutions have a variety of processes by which they motivate and encourage individuals to develop. The strongest influence is through the ascendance of age-based crisis points where the expectation is that the individual will make a turning point by resolving a challenge between two opposing oppositions (e.g., identity formation versus role confusion) during the teenage and emerging adult years. Work and educational systems provide mentors and teachers to help guide and direct youth to make choices through role modeling, instruction, encouragement, and other positive educational techniques. Erikson indicates that the best teachers are ones that know how to balance play with work to make the decision a pleasurable and positive experience. Educational research clearly demonstrates that positive instructors and peers enhance identity formation among students during the high school and college years.

ESSAY TESTS

Essay tests are a type of constructed-response assessment in which test-takers display skills and knowledge by writing responses to an assigned task, question, or prompt. Instead of selecting answers to multiple-choice questions, the test-taker may be required to present an opinion on an issue, explain a chemical process, describe a scene in a foreign language, present conclusions drawn from a set of economic data, write a narrative, or demonstrate other skills and understandings in writing. The tasks may be simple or highly complex, discrete or multiphased; the response format may vary from a paragraph to a letter, a multiparagraph essay, a proposal, and so on.

For centuries, essay testing was the primary form of assessment. But with an emphasis on statistical rigor and the advent of rapid-scanning equipment and other technical advances in the mid-20th century, selected-response tests (primarily multiple-choice tests) emerged as a generally more objective, efficient, and cost-effective form for large-scale assessments. Selected-response tests usually sample a broader content domain: In an hour of testing time, test-takers might respond to 45 multiple-choice questions instead of only one or a few essay questions. Furthermore, the more questions in a test, the less a test-taker's performance on any one question influences the final score. These factors, in addition to the right-or-wrong nature of the questions, make selected-response tests "more reliable"—that is, test-takers' scores are substantially more consistent across different versions of the same test. As selected-response testing evolved, essay testing was often dismissed as more subjective and less reliable.

In recent decades, however, developments in cognitive psychology and an increased emphasis on more authentic assessment have helped spur interest in having test-takers *display* or *perform* certain skills. Essay testing has become a highly rigorous discipline supported with research, technological advancements, and published guidelines for best practices (although theorists continue to debate conceptual issues, including the extent to which test reliability should be emphasized or readers should set aside their personal reactions to essay responses).

Essay testing requires careful deliberation at every stage. The process of specifying the domain of content and skills to be assessed often includes surveys, focus-group sessions, committee deliberations, or reviews of professional and curriculum standards. The development process may also include prototype testing of various formats, directions, topics, and evaluation criteria, as well as questionnaires or interviews ascertaining test-takers' opinions about the tasks. Below are some important steps in designing an essay test:

- Determine which skills and knowledge are best assessed via essay tasks.
- Consider the extent to which writing fluency could unduly affect measurement of other skills or knowledge.
- Include a sufficient number of test questions—possibly combining essay tasks and selected-response questions—for desired content coverage and reliable scores.
- Provide adequate time for each task.
- Consider how requiring test-takers either to hand-write or word process essay responses may affect test-takers' ability to display the skills being assessed.
- Give test-takers ample opportunity to prepare by prepublishing information about the task types and scoring standards, including sample questions and sample responses with scores and commentary.
- Determine the extent to which evidence supports the claim that the essay test is valid for its intended purpose—that is, that the inferences and actions based on test scores will be appropriate, meaningful, and useful. For example, conduct studies to investigate relationships between test-takers' performance on the essay test and demonstrations of the same skills in other contexts.

In essay testing, how responses are scored becomes an integral part of test design. First, the scoring methodology determines what type of information will be obtained. One common approach is *holistic* scoring, in which a reader appraises the overall quality of a response to assign a single score. Holistic scoring can reflect the integrated nature of proficiencies such as writing, reading comprehension, and/or critical-thinking skills; moreover, it is an efficient approach to scoring large volumes of responses. However, it does not provide the diagnostic feedback or detailed information that may be gained from more time-consuming *analytic* scoring, in which a reader may evaluate the different features or traits of a response separately or else award scores based on the presence or absence of specified components (e.g., particular facts about a chemical process). In practice, testing programs may employ variants of holistic or analytic scoring.

Second, to make scoring more reliable, it is important to develop explicit and carefully crafted evaluation guidelines: the *rubrics* or scoring guides that usually require the reader to apply a variety of specifically defined criteria (e.g., accuracy of information, aptness of examples, clarity of expression). Ideally, these criteria embody the consensus of the relevant community of educators and readers. Rubrics also stipulate the scale of numeric or descriptive score levels that readers can assign.

For large-scale testing programs, operational scoring procedures are usually highly structured and standardized. Scoring sessions may be *centralized*, with all the readers gathered together, or *distributed*, with readers geographically dispersed. Distributed scoring can be done online, with readers accessing training materials and scoring responses via an Internet application. Online systems bring great efficiency to the scoring process and allow the scoring leadership to monitor it using up-to-the-minute data on reader performance, including score distributions and rates of interreader agreement.

Scoring protocols that help promote fairness and accuracy include training of readers both before and throughout the scoring session as well as mentoring and monitoring by experienced readers who serve as scoring leaders. Training should familiarize readers with the principles of the scoring methodology, the rubrics, the essay tasks, and the exemplar responses that, for each topic or question, help define each score level in the rubric. As part of the protocols, many testing programs enhance score reliability by requiring that two readers independently score each response, with a third independent reading to resolve cases in which, according to program standards, the initial two scores differ too widely.

The field of essay testing continues to evolve. Recent technological developments include automated scoring by software applications that use semantic analysis or other types of computational approaches intended to emulate the judgments of human readers. Ongoing research and refinements in essay testing are also making it possible to assess a wider range of skills and knowledge and enhance the authenticity of essay tasks.

ETHICS AND RESEARCH

The knowledge base in educational psychology has been developed by individuals who have conducted research to uncover truths about the affective, cognitive, and behavioral attributes of learners. The growth of any discipline is dependent upon the worthiness of the research that it produces. Research is defined as systematic investigation, including research development, testing, and evaluation, designed to develop or contribute to generalizable knowledge. Effective research must meet the criteria of being relevant and ethically produced. When research does not live up to the standards of defined practice, research misconduct inquiries and investigations are used by institutions to identify the objectionable practice and to remediate the affects.

Research ethics is a broad term that is used to describe adherence to the shared values of efficiency, truthfulness, accuracy, and objectivity. Ethical research must use resources wisely and convey information truthfully by carefully reporting results in a truthful manner without bias. A more narrowly focused term—*responsible conduct of research*—relates to more definable practices that prescribe the research behavior required of investigators.

Responsible conduct of research must take into consideration the following eight elements:

1. Data acquisition and management

2. Mentor–trainee relationships

3. Publication practices and authorship

4. Peer review practices

5. Collaborative research activities

6. Protection of human subjects

7. Research involving animals

8. Management of conflict of interest and commitment

More specifically, responsible conduct of research refers to meeting the requirements relating to those concepts mandated by Congress and the regulations promulgated by federal agencies. However, the broader view of research ethics goes beyond what is required and relates to what should be done regarding moral dilemmas that surround how to make the best research decision.

The federal regulations relating to responsible conduct of research stem from three acts passed by Congress: the 1966 Animal Welfare Act (Public Law [P.L.] 89–544), the 1974 National Research Act (P.L. 93–348), and the 1985 Health Research Extension Act (P.L. 99–158). The 1985 Health Research Extension Act resulted, in 1989, in the establishment of the Office of Scientific Integrity (OSI) and the Office of Scientific Integrity Review (OSIR). In 1992 the Office of Research Integrity (ORI) was established and took over the activities of the former two offices, including the monitoring of research misconduct.

In addition to the regulations developed from these acts, the executive branch agencies of the government have developed guidelines and policies that represent requirements relating to their normal operation. For example, the National Institutes of Health has issued policies for grant awards, and the ORI has issued a Model Policy and Procedures for Responding to Allegations of Scientific Misconduct.

Beyond the federal policies are disciplinary codes of ethics and institutional policies. Most disciplines have outlined principles and, in some cases, appropriate practices that relate to the ethical practice of research. Universities and other institutions must also have research policies if they are to receive federal funds. Again, these policies may go beyond the recommendations of the federal guidelines. Many of these policies amplify and implement the federal guidelines that make up the various elements of responsible conduct of research.

Data Acquisition and Management

Issues relating to data acquisition and management include collection of information, storage, ownership of data, and sharing of data.

Collection of information is governed by principles of effective research. The quality of research depends upon the use of appropriate research methods. Investigators need to be precise in the collection and handling of data. The results must be carefully recorded, analyzed, and interpreted. Data can be recorded in numbered bound notebooks, by permanently dated electronic files, or other permanent means.

Information should be stored in a safe place that is not subject to the elements or catastrophes. Electronic files should be backed up and stored away from the original data. Other materials, such as samples or videos, should be protected so that they do not degrade. Confidential information must be stored in areas that prevent unintended access.

Ownership of data that is generated by researchers is a complex matter. There are various parties that may have claims on the ownership of data. The university or the institution that employs the researcher and governmental or foundation funding sources have a stake in the data collected. Researchers must report the results of their work to the granting agencies, but the control of the data generated is the responsibility of the institution that received the funding. If the funding source was a contract, the researcher will be obligated to provide a product at the end of the project. The organization that received the funding has responsibilities to maintain the data collected. Researchers who leave employment at one institution and take a position at another must seek approval to relocate the data that they have collected.

Mentor–Trainee Relationships

Responsible conduct of research includes developing mentor–trainee relationships. Successful researchers have an obligation to foster the development of others who are learning to become researchers. It is the responsibility of a good mentor to help the student capitalize on the educational experience and to acculturate the student into the practices and ethics of the profession. A mentorship relationship requires that the mentor provide a supportive learning environment. The mentor must devote a sufficient amount of time to facilitate the development of the trainee. This will include providing training, supervision, and honest appraisal. The mentor, through example, will teach the basics of data collection, interpretation, and publication and will give due credit to the trainee for his or her contributions. The mentor will help the student

understand the values of the profession and how to maneuver within the accepted guidelines. Included in the culture of the profession is the way it treats authorship and publication practices.

Publication Practices and Authorship

Modern copyright first appeared in Britain in the 17th century to protect the printing industry from others who would duplicate their products. According to Corynne McSherry, eventually the concept of copyright came to encompass protection of the intellectual property of the author.

At most universities, faculty are assigned the copyright for their works of scholarship unless those rights relate to a patentable product. This policy allows faculty to publish freely without restriction and disseminate to the public the results of their research and scholarship. In situations in which research leads to a new discovery that can be patented, publication may be restricted until a patent can be assigned. A patent prevents others from practicing the invention and gives the developer the right to practice the invention or seek licensing allowing others to commercialize the discovery. Premature publication may prevent the establishment of a patent.

Early disclosure of results of research is often provided at professional meetings and is later further documented in scholarly publications. Fair practices of publication require that all documents provide a detailed and objective description of the research that was conducted. It should describe the methods used, indicate the results discovered, and provide an open assessment of the findings.

When individuals collaborate on a publication, it is often unclear as to who will be credited as the main author and who will have a lesser role. Usually authors are listed in publications in the order of the importance of their contributions. However, whereas in some disciplines the most important contributor is listed first, in others this individual is listed last. Disputes can arise regarding the order of authorship when the authors have failed to discuss this issue beforehand. In psychology the code of ethics states psychologists must take responsibility and credit, including authorship credit, only for work they have actually performed or to which they have substantially contributed. In addition, principal authorship and other publication credits must accurately reflect the relative scientific or professional contributions of the individuals

involved, regardless of their relative status. The code goes on to say that minor contributions to the research or to the writing for publications are acknowledged appropriately, such as in footnotes or in an introductory statement.

Although it is recognized that only individuals who have made significant intellectual contributions to an article should be listed as authors, there is no universal understanding as to what constitutes a significant contribution. In an attempt to bring clarity to this ambiguity, the International Committee of Medical Journal Editors (ICMJE) proposed a set of guidelines that are often used. The ICMJE declared that authors must have taken responsibility for portions of the article's content. This could include contributions to the development and design, acquisition of data, or analysis and interpretation of data. The author must have had a role in the drafting of the article or be involved in the critical revision of the content. The author must also be in a position to approve the final version to be published. According to the ICMJE, acquisition of funding, collection of data, or general supervision of the research group would by itself qualify an individual as an author without meeting the previously stated criteria. The ICMJE further stated that the order of authorship should be a joint decision of the coauthors. The greatest contribution of the ICMJE was to suggest that authors should provide a description of what each person has contributed to the article and that others who did not meet these criteria for authorship but had contributed to the article should be acknowledged but not listed as authors.

Responsible publication practices dictate that the same research results should not be repeated in different publications without citing the previous publication. Duplicate publications have the result of wasting time and resources and also tend to overemphasize results beyond their actual importance. A review of the literature would unfairly weigh the results of the research in favor of the author's conclusions when it has been repeated in multiple journals.

Peer Review Practices

Once an article has been written, it is customary to submit it to a journal for peer review by colleagues who have expertise in the topic and can provide a fair review of the manuscript. Peer review helps determine which research is reliable, valid, and should be published and which research has flaws and should

not be made available to the profession. It is a universal process that takes place in all countries and has the effect of professionals monitoring their own professions. In the same way, peer review is also a part of the process that will determine which research will be funded. Grant reviewers will evaluate the concept, methods of research, budget, and potential outcomes of the research.

Peer review becomes an essential ingredient in the career of the individual and influences the direction of research an individual takes within the profession of educational psychology. With so much at stake, it is therefore important that the process be as open as possible and that it have certain safeguards. Peer review must be conducted in a manner that respects the confidentiality of the research and is free from the reviewer's personal bias. The feedback must be critical yet constructive in its nature so that the author may benefit and so that the profession can be protected. It is also necessary that it be completed within deadlines that permit publication in a timely fashion.

Scholars within a profession have the obligation of investing time to review grants and publications within the profession. Individual reviewers should know their limitations when reviewing. They should review only projects for which they are adequately qualified to render an informed opinion. In addition, reviewers should be familiar with the literature in the field, be able to judge the quality of the manuscript, understand the methodology implemented, be knowledgeable about the type of analysis employed, and be capable of evaluating whether or not the conclusion is supported by the evidence. Beyond these requirements, the reviewer must be able to identify any possible conflicts of interests that might exist. If a reviewer is working on the same research as the author, he or she must disclose this conflict to the editors and either excuse him- or herself or be certain to review the material objectively and not use information learned from the review in his or her own research.

Collaborative Research

Collaborative research has many rewards but poses interesting challenges. Before research begins, collaborators must have the same understanding of the requirements, and thus, a uniform level of training and supervision must be in place. This may include an understanding of welfare of human subjects, animal subjects, and use of hazardous materials.

When researchers are working together with others, either on a publication or a grant, the roles and responsibilities of each researcher must be clearly delineated. Collaborative activities require the clarification of the following issues: Who will submit the funding proposal? Who will submit the proposal protocol for evaluation to a subject review board? Who will store the collected data? Who will have the authority to make changes in the project? Who will write the first draft of an article, and who will report the results of the article? How will intellectual property rights be distributed? These issues can be resolved only if effective communication is established among the collaborators.

If the collaborative research entails external funding, financial management can also become an issue. The Office of Management and Budget produces two documents, Circular A-21 and A-110, which provide guidance regarding the financial management. All members of the collaborative team need to be familiar with these documents so that they are aware of allowable expenditures, equipment use, and reporting procedures.

When research involves the use of materials, it is necessary to formulate agreements that address how such materials will be transferred between researchers and their institutions. This is usually accomplished through transfer agreements that stipulate the conditions under which the materials can be used and information that can be disclosed as a result of their usage.

Protection of Human Subjects

Research that involves human subjects must be designed and conducted in a way that maximizes benefits to the subjects while minimizing risks. The process of ensuring ethical treatment of subjects requires that all proposed research be scrutinized by a human subjects review board.

Research practices in the past that failed to protect subjects led to the need for a formalized method for evaluating and approving human subject research. Much of the effort toward protecting human subjects occurred following World War II. Evidence of atrocities committed during the war and attributed to research activity led to regulations known as the Nuremberg Code. This code and the later Declaration of Helsinki established an international framework that defines ethical treatment of human subjects. The Nuremberg Code established basic principles that make

up the expectations for ethical treatment of human subjects. They include the requirement of obtaining voluntary consent of the subject, establishing the benefit of the study in relation to risk, avoiding unnecessary suffering and injury, requiring adequate facilities and qualified experimenters, and allowing the subjects to discontinue involvement at any time.

Even though such guidelines existed as early as 1947, unconscionable research nonetheless occurred following the war. In the United States, research on the effects of radiation was conducted on subjects in hospitals without their consent. In the 1950s and 1960s experiments on the effects of untreated syphilis were conducted on unsuspecting African American subjects by the U.S. Public Health Service in Tuskegee, Alabama. The resulting concern over these and other violations of subjects' rights led to governmental policy. In 1974 three sets of guidelines were developed by the U.S. government. First, the Congress demanded that the Department of Health, Education and Welfare (now Department of Health and Human Services) further address standards for involving human subjects in research. The resulting outcome was Title 45 of the Code of Federal Regulations, Part 46 (45 CFR 46). In a similar time frame, the Food and Drug Administration established its own rules for human subject research (21 CFR 50 and 56). Also in 1974 the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was established. Following these efforts, in 1991 many federal governmental departments and agencies adopted a uniform set of regulations known as the Common Rule, which makes up the guidelines affecting human subject research (45 CFR 46, Subpart A-D). The Common Rule requires that studies involving human subjects be approved by a human subject review board or other appropriate institutional officials. The review board also should provide a continuing review, at least once per year, of the approved research. In some situations, the human subjects review board may identify research as being exempt from the federal requirements. The responsibility of enforcing the Health and Human Services regulations falls upon the Office for Human Research Protections in the Office of Public Health and Sciences. To help ensure that researchers understand the principles of protection of human subjects, the National Institutes of Health requires that investigators who submit a grant application receive training on the protection of subjects. The Common Rule requires that an institution that is engaged in federally funded human subject research must file a Federal-Wide Assurance of Protection for Human Subjects.

Decisions regarding ethical treatment most directly spring from the 1979 Belmont Report of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The principles identified in the report include (a) respect for persons and their right to make autonomous decisions; (b) beneficence, or the need to maximize benefits while reducing risks; and (c) justice, or the obligation to distribute benefits and risks equally among subjects.

Research Involving Animals

Educational psychologists often study the behavior of animals as a way of understanding principles that govern human behavior. Because animals cannot consent to becoming subjects and the research may not benefit them directly, special care must be taken to ensure their best treatment. Just as in the case of protecting human subjects, Congress has developed regulations that address the responsible use of animals in research. Two specific acts, the Animal Welfare Act (1966, 1970, 1976, 1985, and 1990) and the Health Research Extension Act (1985), have provided guidance on responsible conduct. The Animal Welfare Act concerns itself with the transportation, care, and use of animals in research. The responsibility for the regulations falls upon the U.S. Department of Agriculture (USDA) under Title 9 of the Code of Federal Regulations. Guidelines were created from work in the 1950s by the Animal Care Panel, who established a professional standard for animal care in research. This work eventually led to *The Guide for Laboratory Animal Facilities and Care*, first published in 1963 and now titled *The Guide for the Care and Use of Laboratory Animals*. The Public Health Services (PHS) requires that investigators use this guidebook when establishing and conducting an institutional program of animal research. Just as human subject research requires an approval board, animal research has a similar counterpart, the Institutional Animal Care and Use Committee (IACUC). The PHS defines animals as any live, vertebrate animals used or intended for use in research, research training, experimentation, or biological testing or for related purposes. However, educational psychologists intending to use animals for research should take the broadest view possible of the definition of an animal and

should consult with their own institution's IACUC regarding their research.

Based upon the 1985 Health Research Extension Act, PHS Policy, USDA regulations, and the *Guide for the Care and Use of Laboratory Animals*, the IACUC at each institution is empowered to administer the care and use of animals in the conduct of animal research. The IACUC has responsibilities for reviewing and approving all proposals for animal research, evaluating the animal care program of the institution, inspecting the facilities, and responding to concerns about animal care. The IACUC can also exercise independent judgment to suspend research if the guidelines for care and use of animals are not followed. Federal oversight is also provided by the Office of Laboratory Animal Welfare and the USDA.

Research must follow the federal government's Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training. These include guidelines on transportation, care, and use of animals in research; designing research that is relevant to human or animal health, advancement of knowledge, or the good of society; use of appropriate species and the minimum number needed for results; avoiding or minimizing pain, discomfort, and distress of the animals; using appropriate sedation analgesia or anesthesia; painlessly euthanizing animals that are suffering; feeding, housing, and caring for animals appropriately; using only qualified and trained personnel; and consulting the IACUC about any exceptions.

In addition, a voluntary accreditation program is administered by the Association for Assessment and Accreditation of Laboratory Animal Care, a nonprofit organization that accredits programs that pass a detailed inspection. The Office of Laboratory Animal Welfare functions by relying on an assurance or signed agreement that pledges the institution to comply with all regulations and is monitored through an annual report. The USDA uses an inspection mechanism to ensure compliance.

Conflict of Interest and Commitment

Because one of the basic elements of research is that it must be free from bias, it is essential that any possible conflicts of interest or commitment be identified and rectified where possible.

Researchers with similar interests may experience conflict with one another. For example, an educational psychologist studying a new way of identifying anxiety will be interested in the research of others on this topic but may not want to share his or her results until he or she can be protected by copyright or publication. The reviewer who is conducting similar research must recognize a conflict of interest and be certain to protect the confidentiality of the material being reviewed. Conflicts are often inevitable but, in and of themselves, may not be bad. However, the researcher must be aware of them and will need to communicate their existence in order to avoid the perception that the research is unduly affected by the conflicts.

The most common conflicts include those that result in financial gain, those that affect work commitments, and those that involve intellectual and personal matters. Financial gain comes into play when a researcher unfairly delays a competitor's research so that he or she can gain an advantage. A prime example might be giving a lower score on a grant review so that one will have a better chance of getting funding for his or her similar research. At other times financial gain may not be a negative event. According to the 1980 Bayh-Dole Act, investigators and their institutions that receive federal funding are required to disclose their funding through publications, copyrights, commercialization, and other means so that knowledge can be disseminated to the public. This often will result in financial benefit in one form or another.

Conflicts of work commitment can occur when the researcher has committed to more activities than can be easily accomplished. For example, when an individual has accepted too many grants, too many peer reviews, or too many consultantships, a conflict of work commitment may exist. When the overcommitment is due to the competing needs of grants, monitoring of those activities may be accomplished through guidelines established by the Office of Management and Budget in its Circular A-21, which has regulations on how researchers can spend their time.

Conflicts of a personal and intellectual nature affect the honest and accurate conducting, reporting, and review of research. When an investigator draws conclusions that are based primarily upon personal opinion or affiliations, bias can be ascribed to the decision-making process.

Conflicts of all types need to be disclosed to avoid perception of bias in the reporting of scientific evidence. In the 1990s the federal government developed policies through the PHS and the National Science Foundation to address the handling of various conflicts. The policies require the researcher to report

significant conflicts before research is conducted, to manage conflicts of personal gain by reducing or eliminating those conflicts, and to provide information on how the conflicts have been addressed.

Research Misconduct

The volume of research conducted yearly continues to mount. With so many researchers gathering and reporting data, it is inevitable that a small number may engage in unethical practices. Even with so much research, it has been reported by Nicholas Steneck from the ORI that misconduct in research is at or below 1 case for every 10,000 researchers. He warns, however, that the number of confirmed cases may be underestimated and that underreporting is to be expected.

Research misconduct is defined by the Office of Science and Technology Policy as fabrication, falsification, or plagiarism in proposing, performing, or reviewing research or in reporting research results. This definition is similar to earlier definitions established by PHS and the National Science Foundation. Behavior is considered to meet this definition when it is a significant departure from accepted practices, has been committed intentionally or knowingly or recklessly, and has been proven by a preponderance of evidence. Although the federal definition provides a baseline for identifying abnormal practices, it does not address all of the subtle variations that constitute unethical behavior as described earlier in this entry. Therefore, many institutions add to the definition in order to encompass a broader view of research misconduct.

When an institution receives PHS funding, it must put in place a system to address accusations of research misconduct. The mechanism must include the designation of persons who are authorized to receive and investigate allegations of misconduct. It must have procedures for an initial inquiry hearing to determine if the allegations are of merit. For those situations in which the allegations seem to be well-founded, the institutions must have a process to carry out a formal investigation to discover the truth. There must be policies authorizing those responsible for the investigation to impose sanctions or vindicate the researcher and to report the results of the investigation to the ORI. There must also be regulations to protect a whistleblower who provides information in good faith.

ETHNICITY AND RACE

The effects of race and ethnicity are complex and multidimensional and have institutional and social causes. This entry provides definitions for *race* and *ethnicity* in the United States as researchers, scholars, and institutional agencies currently use the terms. Although there are both biologically derived definitions and socially constructed definitions, the biologically derived definitions are being debunked, and a more complex definition, related to *racialization* (i.e., the categorization of people by race, which leads to racial discrimination) is more widely accepted. There are still many weaknesses in how researchers collect information on race and ethnicity, specifically when relying on definitions provided by the U.S. census and assuming that these definitions are consistent. However, it may be that understanding the fluidity of these definitions can allow researchers to improve data collection and data interpretation.

Race, ethnicity, and national origin have a significant impact on the life chances or life opportunities of individuals in the United States, and in the United States, education has become the means by which it is believed people gain social mobility—not solely by what they learn in the classroom but also by the social networks, prestige, and occupational credentials they gain by attending institutions of learning. Therefore, the intersections of race, ethnicity, and national origin are more profound when the disparities in educational

achievements by race, ethnicity, and national origin are considered.

The debate over the racial and ethnic disproportion in educational achievement has traditionally been explained by Linda Darling-Hammond as a process of biological fact. Due in part to the civil rights movement, a growing number of researchers of color, and a greater focus on institutional inequalities and their effects, biologically derived explanations for disparities in educational achievement have given way to cultural deficiencies explanations. Such perspectives have been articulated by Richard Herrnstein and Charles Murray and by Dinesh D'souza. The most infamous of all these works has been the discredited Herrnstein and Murray's *The Bell Curve.* Most of these works ignore the historical and systemic social and institutional barriers that are still in place today.

Defining Ethnicity, Nationalism, and Race

Within the racialization process of the United States, Blacks are at the bottom of the racial hierarchy, Whites are at the top, and other groups are in the political process of managing their positions away from Blacks and closer to Whites. Max Weber, who equated ethnic group identification to a group's belief in a shared historical origin and common ancestry, developed the historical sociological definition of *ethnicity.* In his definition, the emphasis is on belief. An ethnic relationship is believed to be equivalent to a blood relationship among the members of the ethnic group; that is, members of an ethnic group believe they share a common ancestry with members of the same ethnicity. This definition of *ethnicity* has been broadened to include the belief that a shared culture can determine an ethnic identity. Looking at ethnic identity as a process of a shared culture makes ethnic identity a process of the present-day connections between members of an ethnic group. Specifically, it is the culture that they share today that helps to determine their shared ethnic group identity. Stephen Cornell and David Hartmann have argued that this emphasis on culture has complicated ethnic identities and made them less salient. However, even though cultural interpretations of ethnicity have grown in prominence, the belief in a common ancestral original history clearly distinguishes it from other sociocultural groups found in society, such as motorcycle riders, Goths, or even social class. Ethnicity may be less salient, but the meanings of ethnic identity are still important for members of the ethnic groups.

More complex than the definition of *ethnicity* is the definition of *race. Race* has historically been defined by the perceived visibly distinct physical characteristics shared, or believed to be shared, by members of a race, whereas *ethnicity* has been defined as a process of belonging, at least contemporarily. Race is based on what makes others physically different and therefore truly not of the same biological origins. Racial definitions are usually a clearer way of creating otherness. The biological basis or what a person views as distinct traits between individuals marks a group as genetically distinct from one's own, and ethnicity does not have the same function. According to Weber, one becomes aware of one's ethnicity when one comes into contact with a person not of one's ethnic group. However, a distinct ancestry or history does not rule out the possibility of some shared bloodline, even if distant. Race, on the other hand, denies all but the minimal possibility of shared blood relationship. It is this outright biological distinctiveness that is a part of the definition of race that allows not just for the categorization of different racial groups but also for the creation of a hierarchy based on the belief that the visible racial distinctions represent only the surface of greater, more meaningful differences among races. In other words, race has historically assumed a biological distinction, and more importantly, it has inherently assumed a biological hierarchy. Ethnicity, on the other hand, marks cultural distinctiveness. There is, of course, a cultural hierarchy that is manifested by ethnic origins. For example, English and German ethnicities are usually placed higher within these categories than Italian or Greek ethnicity. However, under the proper tutelage, "bad" or "deficient" cultural values can be overcome or improved. Biological "deficiencies" cannot.

Of course, racial categorization has been a process that has continuously shifted in its defined lines. More so today, the biological association that exists with the term *race* has been further debunked by the current biological research that has shown the biological insignificance of racial categorization or the socially constructed nature of racial categories. Michael Omi and Howard Winant have noted that this has validated the claims of many social scientists and, furthermore, allowed for social scientists to show how the definition of race is clearly tied to shifts in political and societal needs and values. However, even though the

definitions of *race* and *ethnicity* are constantly redefined over time, these identities have real emotional and social implications for all the members of society. Housing, occupational, educational, and health opportunities are all affected by racial and ethnic status.

Individuals place themselves within the hierarchy of the racial and ethnic ranks, and much of their psychological identity is based on who they are and what they believe people assume their racial and ethnic origins are. Recent studies on "color-blind racism" provide some insight as to how important race and ethnic identities are, even for individuals who do not have to consider or think about their own racial categories. For example, studies on White undergraduates have clearly shown a valuing or devaluing of other individuals based on their ethnic or racial group.

Joane Nagel argues that ethnicity is a core concept, whereas national and racial categories are aspects of ethnicity. This definition may be a more appropriate definition for understanding the racialization process outside of the United States, and it can provide buffers for new immigrant groups arriving in the United States. For example, the most important factor for Africans in determining their reception in the United States was their race. However, consider the case of West Indians who are often protected from racialization in the United States. If they are assimilated into American society, then for a portion of West Indians, the effect of racialization outweighs their more favorable West Indian ethnicity or that, for some of these immigrants, their West Indian ethnicity provides some protection from a Black racialization. Ethnicity may, therefore, provide a process undergone by new immigrant groups in the United States. Specifically, ethnicity may give members of an immigrant group the ability to integrate successfully within the racialization process, by buffering some members of the immigrant group and allowing them to maintain an ethnic identity and therefore keep themselves from being considered (racially) Black. Nationalism, or the concept of a national identity, is a theoretically complicated idea, especially in the United States where even American Indian identity is proclaimed as a racial definition instead of a national definition, and although there may be political reasons for the exclusion of a national identity among American Indians, the very lack of usage of American Indian nationhood within the United States, as well as in the rest of the Americas, makes a national identity foreign or strictly understood as the identity linked to a territorial space.

However, when the concept of national identity has been used in the social sciences, it has been closely linked to the definition of ethnic identity. Nagel, for example, has defined national identity as chauvinistic, bordering, and articulating national character through history and culture for the eventual purposes of creating statehood or nationhood. What makes Nagel's view of ethnicity so important is its ability to incorporate the global racialization process that took place during the colonization and postcolonization periods. During the colonization period, the racial and ethnic hierarchical concepts from the West were imported and incorporated throughout the world. In the United States a northern European supremacy ideology arose; in Latin America an ideology of approximating or nearing Whiteness developed; and in Africa a process of mimicking Europeanness was formed. What the global colonialization period did was to set up an internal racial or ethnic hierarchy among the colonized nations and within the individuals in these societies that has continued during the postcolonial period. This internalized hierarchy reflects the earlier colonial Western racial hierarchy, although it is bound within the specific context of a postcolonial country's historical colonial experience. The Western colonizers developed a colonial administration that provided opportunities to certain groups within the colonized nation and allowed for the members of these groups to establish themselves as superior within the internally constructed racial strata.

The racialization process becomes more complex when immigrants from Latin America are considered. In Latin America, the descendants of the Spanish *conquistadores* were placed on the top of the racial hierarchy, followed by the *mestizos, mulatos, indígenas*, and *negros*. This hierarchy remained in place throughout the postcolonial period. An interesting phenomenon of the postcolonial national identity construction is how the process has developed a pro-Western or positivist ideology that made Europe the center and the creator of modern cultural, scientific, and progressive societies. The process that determines one's racial position in Latin America may be more complex than that in the United States, but it is still one that is organized around a White or European pinnacle.

These complexities of race and ethnicity are exacerbated for Latinas/os in the United States. When Latinas/os arrive in the United States, they are confronted with the fact that they often are not considered

to be White (as they may have been in their nation of origin), and many, specifically because of their lower economic status, are considered to be more like Blacks. Immigrants who come to the United States must have resources available or a support network that allows for the migration to take place. Even the very act of migrating may be indicative of a psychological orientation that allows for greater risk taking and, possibly, greater rewards.

The U.S. Census and Race and Ethnicity

The U.S. Census relies on Statistical Policy Directive No. 15, Race and Ethnic Standards for Federal Statistics and Administrative Reporting, from the Office of Management and Budget to define *race* and *ethnicity.* Whether they use census data or collect their own data, many scholars use the U.S. Census definitions provided in the decennial census. An interesting consequence of the U.S. decennial census racial and ethnic terms and definitions is the inconsistencies that can exist from decade to decade. The consequence is not that there are changes in the examples used for the racial and ethnic categories but that the very definition of a race can change to include groups previously designated as different, as with Mulattos and Blacks, or to remove groups that were included in a former census, as with Indians (Asians) and Whites. These changing definitions over U.S. history has warranted caution on the part of researchers of race and ethnicity when comparing groups across time and has led credibility to the constructiveness paradigm of race and how racialization happens in the United States.

Critical Race Theory

Critical race theory is an important construct in education and race. Critical race theory is a perspective that has been used by academics of color to help explain, identify, and critique racist elements within the structure of society. The critical race theory framework originates from critical theory, which calls on individuals to actively engage in social critique and social change. Critical race theory attempts to transform these institutional and social elements within the classroom.

Scholars in this area have identified five key elements to applying critical race theory in the classroom: (1) the centrality of race and racism and their intersectionality with other forms of subordination in education, (2) the challenge to dominant ideology around school failure, (3) a commitment to social justice in education, (4) the centrality of experiential knowledge, and (5) the transdisciplinary perspective.

Racial Beliefs or Racism

One of the consequences of having a racial hierarchy is how it becomes justified through primordial or cultural deficiencies explanations. The justification of racial inequalities through primordial explanations relieves the system of responsibility for those who benefit from the racial status quo. Thomas Jefferson found it difficult to dismiss primordial explanations for Black inferiority even when examples to the contrary were abundant. These beliefs are not merely important when attached to political leaders, but such beliefs by individuals in society can continue to manifest racial inequalities through the society. Additionally, when primordial or cultural distinctions become part of a society's discourse, all members, including those least aware, become engulfed in its ideological premises. For teachers, especially White middle-class teachers, this unconscious or conscious belief about race can be highly detrimental to a student of color.

ETHNOGRAPHY

Ethnography is a term that describes a broad range of research activities, including both the process of intensive field research and the textual product representing the results. Although scholars and practitioners debate the nuances of what constitutes the method of ethnography, a hallmark of ethnographic research is long-term fieldwork within a particular environment, setting, or group of people. Ethnography has its roots in cultural anthropology and sociology but is now widely used in many areas of social science, including education.

People frequently equate ethnography with qualitative research. However, not all qualitative research is considered ethnographic. Furthermore, although ethnographers rely heavily on qualitative techniques, they incorporate a wide range of information in their work, including numeric data. This entry discusses unique aspects of ethnography, as well as issues and debates on the topic, but first, a brief history of ethnography is presented.

History

Ethnography emerged in the study of exotic cultures in the late 1800s and early 1900s, because the scientific method of hypothesis testing seemed unsuitable for studying the complexity of human societies. Ethnography grew in popularity because it emphasized listening to group members in natural settings rather than manipulating subjects under contrived experimental conditions.

Anthropologist Bronislaw Malinowski was an early pioneer in ethnography, publishing a groundbreaking study of the Trobriand Islanders of New Guinea in 1922. Almost a half-century earlier, Frank Hamilton Cushing's study of the Zuni people of the American Southwest for the Smithsonian Institution was the first example of an anthropologist living with the people he studied for an extended period of time. Sociology also relies on ethnographic methods. In the 1920s and 1930s, the Chicago School of sociology studied inner city issues firsthand, such as crime and vice, homelessness, prostitutes, and gangs. Ethnography became popular in educational research in the 1970s in studies with school-age students. Schools, classrooms, playgrounds, and teacher's lounges constitute some of the many areas of ethnographic exploration in education.

Unique Characteristics of the Ethnographic Process

As mentioned at the outset, ethnography as a process relates to a family of methods involving researchers' sustained immersion in particular social or cultural contexts. Specifically, ethnography differs from other types of research in its study design, the process of data collection, and the role of the researcher.

The process of ethnography begins with a broad research question or focus, but the emphasis evolves during the course of fieldwork. The design of ethnographic research does not follow a predetermined course. Instead, meaning is constructed through an iterative process of gathering information, refining questions, and analyzing insights throughout the researcher's extended firsthand experiences among community members.

Participant observation is a fundamental method of gathering ethnographic data. It reflects the researcher's active participation in the community's daily life, simultaneously experiencing, observing, and recording social interactions among individuals in their natural environments. Although the unwritten rule in anthropology has been for fieldwork to extend across four seasons of a yearlong engagement, studies today are often compressed into a much narrower time frame. Modern ethnography, particularly outside of anthropology, also finds the researcher engaged in community activities but perhaps not living among community members. In addition to gathering information through participant observation, ethnographers also learn from interviews, key informants, and textual and visual materials.

The ethnographer's role in pursuing an insider's perspective is not that of a detached observer of events. Instead, the ethnographer is an integral part of constructing meaning through actions in the field, personal observation, and the ethnographic path followed. The ethnographer enters the community ignorant of the group's social practices and must rely on members' willingness to share their knowledge. As a result, community members are often referred to as collaborators, colleagues, or coauthors rather than participants.

Unique Characteristics of the Ethnographic Product

In addition to aspects of the ethnographic *process* just explored, the ethnographic *product* itself possesses unique characteristics. Internal validity is the primary gauge of an ethnographic text's quality. An ethnography must reveal the researcher's knowledge construction process clearly enough that readers can evaluate the text's claims. An ethnography's value is in its ability to provide a thorough, convincing, and richly detailed presentation of the insider's view of a specific situation rather than to generalize findings to other settings. Furthermore, ethnography's goal is not reliability or replicability over repeated observations. In fact, different researchers with different perspectives could generate multiple ethnographies from a given research setting. This is not to say that any version would be acceptable; rather, any one of the many possible ethnographies would require the researcher to demonstrate the ethnographic path leading to the claims made by the text.

Issues and Debates Surrounding Ethnography

Criticisms of ethnography revolve around the perceived lack of structure surrounding the research process, subjectivity involved, and the impossibility of generalizing results to other contexts. Ethnographers would argue that these limitations reflect strengths of the approach relative to hypothesis testing research. For example, lack of structure in research design allows for a full range of possible learning to emerge rather than results limited by the constraints of a specific hypothesis. Critics also claim that ethnography lacks sufficient controls for ensuring objectivity. Again, ethnographers would counter by arguing that

no research is apolitical. They would suggest that all researchers bring their own biases and perspectives to their studies, starting with the choices of research questions and study designs. The ethnographer's unique perspective is evident in the text, allowing readers to judge its influence on the work. Finally, ethnographers contend that a lack of generalizability is the price ethnography pays for rich detail and an in-depth insider's perspective.

Clearly, ethnography does not seek the same kinds of knowledge as hypothesis testing research. Ethnography has its own unique strengths and limitations. The strengths of both hypothesis testing research and ethnography are important to the pursuit of knowledge because neither one alone is appropriate for addressing the wide range of human issues to be studied.

EVALUATION

Evaluation can be defined as disciplined inquiry to determine the worth or merit of things, where things may include programs, products, procedures, or objects. Although there is agreement about the desirability of conducting evaluations that lead to such value judgments, there are numerous related evaluation activities and models that do or do not do so. Those have been called *pseudo-evaluations* because they lack such judgments. These less-than-formal

evaluations may be a piece of a larger set of evaluative activities, or they may be self-contained studies that do not identify the value issues embedded in what is being evaluated. In addition, it is possible that they are based on points of view that eschew making judgments of worth. These differences of opinion emerge from the complexities of defining, implementing, and reporting evaluation studies as they attempt to deal with the issues discussed in this entry.

Evaluation and Research

It may be informative to distinguish activities construed as evaluation from those usually associated with research. Although there is no simple way to differentiate between the two, there are three dimensions on which they may differ. First, an evaluation need not have as its objective the generation of "new" knowledge. Evaluation is applied; research is basic. Second, evaluations produce information that is used to make decisions or form the basis of policy. Evaluations yield information that has immediate use; research may not. Third, an evaluation should be, finally, a judgment of worth. True evaluations result in value judgments; research need not and some would say should not.

Personnel Evaluations

Personnel evaluations involve making judgments about an individual's performance as well as contributions to his or her work while providing guidance to improve the individual's performance. Personnel evaluations intend to be unbiased, moral, reasonable, sufficient, and precise assessments of an individual's work. Generally, persons are evaluated over a specified time period with a particular model or approach.

There are multiple personnel evaluation approaches and systems. Most systems, however, determine individual effectiveness and contributions to their organizations as they relate to personal goals or workload agreements. Usually, the evaluations are conducted with predetermined and agreed-upon instruments, standardized categories of professional contributions and growth, and jointly acceptable goals. Scoring rubrics are applied to each evaluation category. The results of personnel evaluations are used for decisions about promotion, salary adjustments, additional training, or other personnel matters.

Program Evaluations

Program evaluations, perhaps the most popular form of evaluation, are systematic inquiries into the value, merit, and worth of educational, medical, or training programs. Proper program evaluations include not only an estimate of the effects of the program but also judgments about materials associated with the program, possible side effects of the program, and the worthiness of the goals of the program. Program evaluations can determine the quality or effectiveness of programs and provide ways to improve the program. For the most part, this encyclopedia entry describes issues and procedures related to program evaluation because of its relative popularity.

The Special Place of Goals

Evaluation studies are set in contexts where goals, standards, outcomes, or similar targets for improvement have been identified. How the goals are articulated and the importance attached to them form the basis for judging the object being evaluated. It is generally acknowledged that defining the goals specifically and rigorously is an essential first step for defining the program or project and directing the evaluation. There are those, however, who would disagree with the statement and advocate goal-free evaluation—evaluating what has been accomplished rather than what was envisaged.

Nevertheless, goals are subject to evaluation as well. A true evaluation makes a judgment of worth about the goals themselves. That judgment moves the evaluator away from a "goal attainment" model (no matter how stated or how determined, the purpose of the evaluation is to decide whether the goals have been met), to a more sophisticated evaluative stance. If, for example, the goals are trivial, it matters not whether they are met. On the other hand, a program seeking to promote high standards and attain substantively important goals can be successful even if the goals are not completely met.

There are positive reasons as well for an evaluator to make judgments about the goals: It may be the case that the goals need to be defended. For example, the goals of subject-matter curricular areas are susceptible to criticisms about the goals. "Fuzzy" mathematics has been criticized because hypothetically students do not learn to compute well. Evolution has been criticized because it is just a "theory." On the other hand,

intelligent design has been trumpeted as a competitor to evolutionary theory. In each of these cases, an evaluator and an evaluation should have a defense about the appropriateness of the goals. The needs of students and learners should dictate the appropriateness of the goals.

The level at which the goals are articulated and to whom they apply are potential pieces of an evaluation. For example, educational institutions or other organizations may have goals that are not directly related to the students they deal with. A college or university may seek, for example, to increase its retention rate or aspire to national recognition of its programs. In achieving those goals, the institution may not have affected how well a student in that institution is educated. On the other hand, if the institution had goals related to a newly defined general education program, it should have direct effects on students. It is an important part of an evaluation to determine who the audience is for both the set of activities and the outcomes of the evaluation. Those audiences are called *stakeholders* in the evaluation literature and have various degrees of affiliation with the program and potential impacts, both direct and indirect, from the program. Also, the goals may be more appropriate for one group than for another.

If an evaluation focuses on just the stated goals of a program or project, it is likely to miss important outcomes. The search for side effects and unintended consequences, both positive and negative, should be as important a focus for an evaluation as is the judgment about the goals and the attainment of the goals. For instance, an increased emphasis on drill and practice in a mathematics curriculum could have the unintended effects of increasing or decreasing students' interest in the subject or making them more or less able to solve problems. If a civics curriculum did not include a set of goals related to civic participation, it would be an inferior curriculum no matter what else it did. Also, it might have goals that preclude active civic participation, in which case it would immediately be considered undesirable. To the extent possible, a true evaluation identifies all of the important effects despite whether or not they are articulated by the goals.

Formative and Summative Evaluation

Whereas the *goals* of an evaluation are judgments of worth or value, the *roles* of evaluation may be either formative or summative. Formative and summative distinctions typically apply to the focus and timing of the evaluation. If the evaluation is focused on the early stages of a program or project, and the intent is to provide information to the developer that can be used to change that program or project, the evaluation is a formative one. If the evaluation seeks to make a final judgment about the object, the evaluation is a summative one. Just as is true for other distinctions, whether a particular evaluation effort is formative or summative can be the subject of discussion. Michael Scriven first made the distinction between formative and summative evaluations in the late 1960s.

Federal agencies, such as the National Science Foundation, often expect both internal and external evaluators of their projects. The roles of these evaluators overlap substantially with the notions of formative and summative evaluation. Although neither is necessarily relegated to one approach, the internal evaluator attends to issues most closely related to formative aspects of an evaluation; the outside evaluator tends to focus on the summative aspects and the overall effects of the program or project.

Change Over Time

The nature of many evaluations is to show change over time. Some evaluation methodologies provide baseline data and structure the evaluation to show growth from that baseline. Perhaps too infrequently, evaluations are designed to show whether there are enduring effects as well, by including a long-term follow-up study. When the intent of educational programs is to produce growth or change, a summative evaluation should determine the amount or type of change from the beginning of the program to the end. Formative evaluations provide direction for improving the program during the time frame defined by a baseline and an end point. The summative evaluation is focused on the difference between the beginning and the end.

Needs Assessments

New projects or programs should be designed and implemented to respond to a particular set of needs for a specific set of purposes. How the needs are identified and justified are questions of a needs assessment. A *needs assessment* is an evaluative process used to determine whether proposed changes are both merited and necessary. Needs assessments determine desirable improvements of a program, curriculum, or

aspects of a professional training and materials associated with a program. Needs assessments use a variety of methods to ascertain the conditions that need to be changed. Those methods include the documentation of performance, completion of specified tasks, observations, classroom data, and examination of current research evidence. Needs assessments evaluate current practices and determine needs for future trainings or programs. One set of judgments about the effectiveness of an intervention involves examining the relationships between the initial needs assessments and the end products of the program or project.

A caveat is that needs assessments may not discover needs. Needs assessments may actually uncover symptoms of needs in the forms of programmatic problems or desirable changes sometimes described as wants. Determining what are wants and what are needs is an extraordinarily important facet of a needs assessment.

Costs and Benefits

Because most evaluations are concerned with improving something and making life better for participants, it makes sense that, to some greater or lesser extent, evaluators would adopt utilitarian views of the enterprise. To the utilitarian goal of making things better for more persons, one can add that it is often desirable to be able to choose among competing alternatives and determine not only whether the outcomes are desirable but also whether one is getting the largest effect for each unit of effort. One way to address such concerns is through a cost analysis.

Cost analyses take varied forms including cost feasibility, cost-effectiveness, cost-benefit, and cost utility. To assess all of the costs, however, it is necessary to go beyond financial concerns (what does the program cost monetarily) to attempt to measure all of the costs, including such things as psychological costs, if any, to participants. In addition, economists talk about opportunity costs, those costs that are related to what other things could have been done rather than what had been done.

Cost analyses, especially cost-benefit analyses, are not easy things to do. Despite the difficulty of assessing the costs of an educational program or intervention, costs may be easier to delineate than are the benefits of that program or intervention. Enumerating benefits can be costly and time consuming. A cost-benefit analysis is often called for by those who wish

to make the judgments of worth discussed earlier. Educational programs, for instance, can provide experiences that have both short- and long-term effects. Without proper follow-up studies, therefore, the prudent evaluator may wish not to claim that a cost-benefit analysis has been conducted.

An evaluator should not eschew cost analyses simply because they are difficult. Both the effects of the intervention and the amount of time and money devoted to the evaluation should be viewed in some sensible way in terms of whether consumers are "getting their money's worth."

Professional Organizations

Professional organizations produce and orchestrate frameworks and structures of professional practice for evaluations. These organizations function as forums where professionals discuss varied perceptions and approaches to conducting evaluations and understanding evaluation processes. Professional evaluation organizations intend to improve evaluation theory and practice. At the annual conventions of the American Evaluation Association, the American Educational Research Association, and the American Psychological Association, professionals present and discuss evaluations, evaluation models, and evaluation theories with the goal of improving practice in mind.

Professional Standards

The professional evaluation standards developed by the Joint Committee on Standards for Educational Evaluation are used to guide and structure evaluations of educational and training programs, as well as other projects and materials. The standards hold evaluators accountable for making useful and accurate conclusions of merit and worth of the objects being evaluated. Evaluation standards include utility standards, feasibility standards, propriety standards, and accuracy standards. *Utility standards* require an evaluation to be useful to the various participants, audiences, and stakeholders. The utility of an evaluation depends on having met the needs of those affected (stakeholders) by the program or product being evaluated. *Feasibility standards* require evaluations to be practical, realistic, and sensible. Evaluations, therefore, need to be conducted with only the necessary levels of assets such as time, personnel, or materials. *Propriety standards* guard the rights of those participating in the

evaluation. Rules for the study of human subjects and issues related to confidentiality guide the propriety standards. *Accuracy standards* require that conclusions about merit and worth be justified and true. Conclusions about merit and worth derive from accurate and defensible evidence collected in the evaluation.

Even though there are such things as evaluation standards, evaluators and consumers of evaluations still need to make judgments about the desirability of any of the given standards.

A Model for Evaluations

There is a plethora of evaluation models, problems, and examples. They come from most of the traditional disciplines of the social sciences, humanities, and, of course, the field of education. The National Science Foundation has published a brochure, "User-Friendly Handbook for Mixed Method Evaluations," to guide evaluators who wish to approach an evaluation from a variety of perspectives. Mixed method evaluations bridge the gap between those who view evaluations in terms of social science methods and those who view them in more ethnographic terms.

Figure 1 suggests one way to define approaches to evaluation studies. An evaluator chooses one or more of the existing evaluation models, applies his or her skills to a problem, and conducts a study within a set of constraints. The three dimensions are general. The particular labels represent, more or less, the subset of skills and problems that will be addressed in an evaluation.

General Models

1. *Traditional.* An emphasis on consistency between goals, experiences, and outcomes—goal attainment models

2. *Decision oriented.* An emphasis on collecting information from a variety of sources to provide a basis for giving information to decision makers and improving the program or product

3. *Case study.* An emphasis on using a variety of ethnographic methods to understand activities and values and on being responsive to diverse audiences

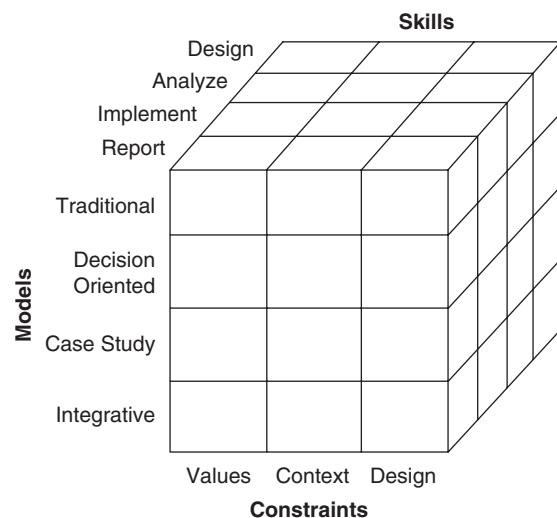
4. *Integrative.* An emphasis on identifying crucial issues, side effects, and costs and benefits and making defensible value judgments


Figure 1   A heuristic for viewing evaluations

Source: Edward Kifer.

These models may incorporate different modes of inquiry. That is, a traditional evaluation focusing on goal attainment could randomly assign units to some treatment and determine the effectiveness of that treatment. A case study could include more than one setting so that comparisons could be made between the effects in one location versus those in another. The particular methods of gathering evidence—experimental, quasi-experimental, and nonexperimental designs—depend not so much on the model that is adopted as on the questions being asked and the resources available to answer them.

Presently there is a major dispute about the desirability of using methods other than randomized controlled trials or experimental field trials in either evaluation or research studies. Experimentation is called the gold standard methodology and is placed at the top of a hierarchy of possible research and evaluation methods. Experimental studies are considered the most desirable way to ascertain the impacts of programs and to determine cause and effect in such studies.

The emphasis on the superiority of experimental methods has met with considerable criticism. Responsible critics acknowledge the power of experimental methods in certain settings for specific purposes. It is generally acknowledged that a well-designed randomized controlled trial can ascertain specific effects and assign cause. However, circumstances surrounding an evaluation may make it extremely difficult to conduct

an experiment. For example, the resources available for an evaluation may not be sufficient to conduct a randomized field trial. The setting for a program may preclude the proper implementation of the program and, therefore, give erroneous results. It may not be possible to randomly assign participants to treatments, for example, to smoking and nonsmoking conditions. Critics argue that the issue is not the desirability of experimentation; rather, it is determining the extent to which it is possible, given a particular setting, to design an appropriate experiment and be able to maintain its internal validity. The fidelity of the treatment is essential.

Additionally, not all evaluations are on such a large scale that the resources are available to conduct either an experiment or a quasi-evaluation. Evaluations conducted in local settings with limited resources can still produce important and useful information. School systems and individual schools may seek information about one practice or another or about one approach versus another. The approaches and skills mentioned here may be sufficient to produce defensible answers to proposed problems. Big is not always good in evaluations.

Skills

1. *Design.* An emphasis on asking appropriate questions and gathering evidence that responds to those questions

2. *Analyze.* An emphasis on procedures and instrumentation that are congruent with the proposed evaluation design

3. *Implement.* An emphasis on data collection and data analysis; a search for consistency between this and (1) and (2)

4. *Report.* An emphasis on writing for an appropriate audience; reporting complex results in straightforward, understandable ways. Differentiating reports for varied audiences and stakeholders

There is great diversity in what an education evaluator is asked to evaluate. It can be something as short as a professional development presentation to a huge curriculum project. Much of the debate about proper methodology is set in a context of large programs with substantial evaluation budgets. However, not all (and probably a small percentage of) evaluations are of that type. Still, the evaluator has the difficult task

of making sure the evaluation contains a sound set of potentially answerable questions no matter how "small" the evaluation.

The design of the evaluation follows the questions to be asked about the object being evaluated. It is, of course, constrained by the available resources and the setting in which the evaluation occurs. Still, consistency between what is to be ascertained and how it is to be ascertained is crucial. Although there are arguments about the efficacy of ethnographic techniques in evaluation studies, few deny that how a program is implemented is a crucial factor in its success. The most obvious way to assess the "fidelity" of the treatment is through observational methods.

Technical concerns are important, too. The proper selection or construction of an evaluation tool can influence greatly the results. Sometimes there is little information to guide the evaluator. For example, although constructed response items and tasks are increasingly popular in educational assessment and evaluation, little is known about how best to design them. Technical concerns such as reliability, interrater consistency, and rubric specificity have trumped design issues. How and what is collected must be congruent with the goals of the evaluation. Such concerns suggest a substantial training need of potential evaluators— technical expertise.

A proper assessment of the evidence is the bridge between the important questions and the reporting of the results. An insightful analysis, be it a statistical or a content analysis, of the evidence provides the means to inform a variety of audiences of the purposes, goals, and effects of what is being evaluated. Multiple methods are often needed to produce the types of evidence needed for a proper analysis of the thing being evaluated.

Whereas the writer of a typical research article typically wants it published in a highly ranked, reputable journal and thus aspires to statistical sophistication demonstrating the newest techniques, the evaluator has the task of communicating important findings to a variety of audiences. Defensible evaluation publications range from a one-page glossy flyer to a well-crafted CD. In between are short reports targeting particular audiences and persons. The evaluator should choose carefully how to approach a particular audience and how sophisticated to make the presentation of the evidence. It should go without saying that the evaluator tells the same basic story to different audiences, just in simpler or more complex ways.

Constraints

1. *Values.* An emphasis on what it means to evaluate (make judgments of worth); identifying the values issues embedded in the evaluation, looking at value orientations, and discerning potential value conflicts

2. *Contexts.* An emphasis on how a setting of an evaluation impinges on what can be done effectively

3. *Design.* An emphasis on how a design of an evaluation can affect the type and strength of conclusions that might be reached

It would be interesting to know whether an evaluator has ever believed that he or she has sufficient resources to conduct the evaluation that is needed. Although resources, both financial and human, constrain what can be done by the evaluator, there are other constraints as well.

An evaluator should attempt to make judgments of worth of what is being evaluated. That means it is necessary to identify the values issues inherent in the evaluation, through the needs assessment or relevant professional literature and standards, and make sure that those issues are addressed in all aspects of the evaluation. The design must include provisions for collecting appropriate evidence so proper analyses and reporting of the values issues are a central part of the evaluation.

A good example of how contexts influence what can be done in evaluations is in the international arena and the evaluation of educational achievements. Participation by countries is often conditioned on observing traditions about what can be tested and how. On the home front, one example is what can be taught (e.g., evolution in some states). These constraints influence the very nature of comparative evaluation studies.

Finally, the evaluation question and the design determine what will be found. What goes in comes out. The evaluator must recognize that there is another day and another set of evaluations.

EXPERIMENTAL DESIGN

An *experimental design* is a specific strategy employed in research to answer a question of interest. In the field of educational psychology, accumulation of knowledge is based on research. For example, an educational psychologist may wish to address the question of whether or not a specific method for teaching mathematics to primary school children results in superior performance on a standardized test when contrasted with an alternative method. Another educational psychologist might conduct a study to determine whether or not noise negatively affects the reading ability of children whose school is situated in close proximity to an airport.

The three research strategies typically employed within the discipline of educational psychology are *observational research*, the *experimental method*, and *correlational research*. Whereas observational research is typically informal and subjective, the experimental method is formal and objective. Alternatively, whereas the observational method sacrifices precision for relevance, the experimental method sacrifices relevance for precision. The use of the term *precision* in defining the experimental method implies the two elements of *control* and *precise quantification*, both of which are lacking in observational research. On the other hand, the use of the term *relevance* in defining observational research reflects the fact that the latter method observes human behavior in the natural environment as opposed to studying it in under the artificial conditions associated with the laboratory experiment. A hybrid of observational and experimental research is the *field experiment*, which attempts to utilize experimental methodology to study behavior in the real world. Correlational research also attempts to provide some balance between precision and relevance, in that it can quantify the behavior of people in the real world, yet at the same time employ statistical means to impose some sort of control over the phenomenon being studied. The general subject of experimental design is most germane to research that employs the experimental and correlational methods.

Basic Definitions

The British statistician Ronald Fisher was primarily responsible for developing modern concepts of

experimental design within the framework of agricultural field experiments he conducted at the Rothamsted Experimental Station in England during the period 1919 to 1939. Among other things, Fisher introduced the concepts of randomization; blocking, which can be employed to control for extraneous variables; and factorial designs, which allow the researcher to simultaneously study the impact of multiple variables.

Regardless of the experimental design one employs, prior to conducting a study a researcher should specify a methodology that optimizes his or her ability to utilize the appropriate type of data to answer the question of interest in as efficient and precise a manner as possible. Among other things, sound experimental design involves identifying and controlling for potential sources of unwanted variability, as the latter can compromise one's ability to identify a cause-effect relationship between the variables of interest. It is important to note, however, that ethical and institutional considerations will often impose practical limitations on the type of research deemed acceptable. Consequently, the challenge to any researcher will be to design an ethically acceptable study that provides experimental control, yet at the same time has enough experiential realism such that the researcher will be able to generalize the behavior of subjects beyond the environment in which they are studied.

The most common type of hypothesis evaluated within the context of an experiment is a prediction regarding the relationship between two variables—specifically, an *independent variable* and a *dependent variable*. The independent variable is commonly referred to as the *experimental treatment*, because it represents whatever it is that distinguishes the groups employed in an experiment from one another. The number of groups employed in an experiment represents the number of *levels* of the independent variable. The measured responses of the subjects in an experiment represent the dependent variable, and if the experimenter's hypothesis is accepted, the magnitude of subjects' scores on the dependent variable should depend on the level of the independent variable to which subjects were exposed.

True Experiment Versus Natural Experiment

A distinction is often made between a *true experiment* and a *natural experiment* (which is often referred to as an *ex post facto study*). The true experiment (which

is referred to also as a *true experimental design*) is considered the gold standard of experimental design. In the simplest type of true experiment, subjects are randomly assigned to either an *experimental group* or *control group*. The experimental group only is introduced to a specific treatment manipulated by the experimenter to determine whether or not the treatment influences the behavior of subjects with respect to the response of interest, which will represent the dependent variable.

Although, because of practical or ethical considerations, it may not always be possible for a researcher to design a true experiment, the latter type of experiment optimizes one's ability to identify an existing cause-effect relationship between an independent and dependent variable, as well as to rule out one or more alternative hypotheses. The defining characteristics of a true experiment are that each of the subjects is *randomly assigned* to one of two or more groups and that the independent variable is manipulated by the experimenter. Random assignment optimizes the likelihood the groups will be equivalent to one another prior to the introduction of the experimental treatment.

At the conclusion of a true experiment, a researcher employs an inferential statistical test to determine whether or not there is a statistically significant difference between the mean scores of the two groups on the dependent variable. If a significant difference is obtained, it is likely to be due to the independent variable. It is important to note, however, that sound experimental design is a prerequisite for meaningful statistical analysis. A statistical procedure applied to a faulty experimental design will, for all practical purposes, be useless, because such a procedure is little more than an algorithm that is incapable of judging the suitability of its use.

To illustrate a true experiment, assume 100 students are randomly assigned to two different groups, each of which will be taught mathematics by one of two methods to be identified as Method A versus Method B. It will be assumed that all 100 students will be taught in the same school at approximately the same time of day (specifically, one class at 10 a.m. and the other at 11 a.m.) by the same teacher. Note that random assignment of subjects to the groups optimizes the likelihood that before being introduced to the two teaching methods (which will represent the independent variable), the two groups will be equivalent with respect to, among other things, math achievement (which will represent the dependent

variable). At the conclusion of the study, if students taught by Method A perform significantly better on a standardized math achievement test than students taught by Method B, the researcher would have a strong basis for concluding that Method A is superior to Method B for teaching mathematics.

The feature that distinguishes the true experiment from the natural experiment is that in the natural experiment, subjects cannot be randomly assigned to a group. This is because in a natural experiment, the variable that distinguishes the groups from one another is not manipulated by the experimenter but instead is a preexisting subject characteristic, such as one's gender or race. Although some researchers employ the term *independent variable* to refer to the variable that distinguishes the groups from one another in a natural experiment, others limit the use of the terms *independent* and *treatment variable* to the grouping variable employed in a true experiment. Consequently, terms such as *subject variable* or *attribute variable* may be used to designate the grouping variable employed in a natural experiment.

To illustrate a natural experiment, let us assume an educational psychologist wishes to compare the efficacy of the educational systems of two towns, Town A versus Town B, each of which comprises 1,000 students. The psychologist conducts a study in which he or she compares the scores of students in the two towns (which will represent the independent/grouping variable) on a standardized academic achievement test (which will represent the dependent variable). Results show the average score of students in Town A is significantly higher than the average score of students in Town B. Because the subjects employed in the study were not randomly assigned to the two groups (i.e., towns), the researcher will not be able to conclude that Town A has a superior educational system. Although the observed difference in academic achievement may, in fact, be due to Town A having a superior educational system, extraneous variables (such as socioeconomic status, environmental conditions, etc.) could also account for the difference. Any extraneous variable that is beyond the control of an experimenter by virtue of the fact that subjects are not randomly assigned to groups represents a potentially *confounding variable.* A confounding variable is any variable that systematically varies with the different groups. Because subjects are not randomly assigned to groups, the natural experiment is much more subject to confounding than the true experiment, and

because of the latter, if a difference between groups is obtained in a natural experiment, it does not allow a researcher to draw conclusions regarding cause and effect. For example, in the study under discussion, it is possible that the parents of students in Town A provide their children with more intellectual stimulation outside of the classroom than do the parents of students in Town B, and it is the latter variable, rather than the different educational systems, that is primarily responsible for the superior academic performance of students in Town A.

In the final analysis, the type of information one can acquire from a natural experiment is correlational in nature. Correlational information only allows a researcher to conclude a statistical association exists between the grouping variable and the dependent variable. Thus, given the design of the study that was conducted, although the researcher can conclude that higher academic achievement is associated with Town A, he or she cannot pinpoint the cause of the difference.

It should be noted the most elementary type of correlational design involves evaluating the scores of subjects on two variables to determine whether or not they are statistically associated with one another. A major goal of such research is to determine whether a subject's score on one of the variables, referred to as the *criterion variable*, can be predicted from his or her score on the other variable, referred to as the *predictor variable*. For example, a correlational design might investigate whether there is a predictive statistical relationship between the number of out-of-class activities a student participates in and a student's grade point average. More complex correlational studies can be designed that involve more than one predictor variable and one or more criterion variables.

Internal Versus External Validity

An experiment is said to have *internal validity* when its design is such that the researcher can rule out the likelihood of confounding variables. Although even with random assignment of subjects to groups there still remains the possibility of confounding, the latter is minimal, and consequently, in contrast to the natural experiment, a true experiment will typically be viewed as having internal validity. Consequently, if a significant difference on the dependent variable is observed between groups in a true experiment, a researcher will be able to argue the difference is due to the independent variable.

If the results of an experiment can be generalized, it is said to have *external validity.* More specifically, if the behavior of subjects on the dependent variable can be generalized to other persons, places, and time periods, a study will have external validity. Realistically, however, the external validity of most experiments will be limited, in that the degree to which the results of a study may be generalized will typically be limited to individuals who are comparable to the subjects employed in the study. Additionally, when a study is conducted in a laboratory or some other controlled setting, the results may not generalize to the behavior of people outside of such settings. As noted earlier, a researcher will be challenged to design a study that achieves a reasonable balance between experimental control and experiential realism. Typically, the greater the internal validity of a study, the lower the external validity, and vice versa. With respect to the latter, the true experiment is often depicted as being high in internal validity yet low in external validity, whereas observational research is depicted as being high in external validity yet low in internal validity.

Threats to Internal Validity

Donald Campbell and Julian Stanley made an important contribution to the literature on experimental design when they made a distinction between *preexperimental designs*, *quasi-experimental designs*, and *true experimental designs.* These authors noted that unlike the true experimental design, both preexperimental and quasi-experimental designs lack internal validity by virtue of the fact that subjects are not randomly assigned to experimental conditions or because a study lacks one or more control groups. A study characterized by either of the latter will not allow a researcher to effectively isolate cause and effect with respect to the relationship between the independent and dependent variables. Lack of internal validity associated with preexperimental and quasi-experimental designs can be traced primarily to the potential impact of the following potentially confounding variables: history, maturation, instrumentation, statistical regression, and mortality.

History can be defined as events other than the independent variable that occur during the period of time that elapses between a pretest and a posttest on a dependent variable. To illustrate the potential impact of history as a confounding variable, consider a hypothetical study that represents an example of a *one-group pretest-posttest design*, which is one example of a preexperimental design. Assume that 100 high school juniors are administered the SAT exam in September (which represents the pretest), after which they take a 3-month course designed to improve SAT performance. The students are then administered the SAT again in January (which represents the posttest). In the study, the SAT course can be viewed as representing the independent variable (i.e., the experimental treatment) and the difference between the pretest and posttest scores of the students as the dependent variable. If, in fact, students' January SAT scores are significantly higher than their September scores, the researcher might be tempted to attribute the increase to the SAT course. One cannot, however, rule out the possibility the increase might have been due to some other variable that was also present between September and January. For example, it is possible that during the 3 months students were enrolled in the SAT course, their classroom teachers presented lessons that were responsible for the increase in SAT performance. Consequently, without a control group composed of a comparable group of students who also took the SAT in both September and January but who did not take the SAT course, one would not be able to effectively rule out history as a potentially confounding variable.

A second threat to internal validity is *maturation*, which refers to developmental changes of a biological or psychological nature that occur within an organism as a result of the passage of time. Among other things, during the course of a study (which can be brief in duration or span a period of many years) subjects may grow stronger, become more or less agile, become fatigued, or become more or less intelligent. To illustrate the potential impact of a maturational variable on a dependent variable, assume 100 two-year-old children, who are identified, based on a pretest, as below average in visual-motor coordination, are provided with physical therapy. After 6 months of physical therapy (which represents the treatment variable), the posttest scores of the children are significantly higher than the pretest scores. Although one might surmise the physical therapy was directly responsible for the change in visual-motor coordination (which represents the dependent variable), it is entirely possible the improved performance of the children could have been due to physical maturation and that, in fact, the physical therapy had little or

nothing to do with the change in visual-motor coordination. Consequently, without a control group of children who were not provided with physical therapy, the researcher would not be able to effectively rule out maturation as a potentially confounding variable.

Instrumentation refers to inconsistencies with respect to the accuracy of the instruments employed to measure a dependent variable over a period of time. Such things as instrument malfunction or fatigue or boredom on the part of human observers charged with recording the responses of subjects are instrument-related examples that can compromise the internal validity of a study. *Statistical regression* is the phenomenon that a subject who obtains an extreme pretest score on a dependent variable will be more likely to yield a posttest score on the same variable that is closer to the mean. Consequently, in some instances, a change in a subject's posttest score can be the result of regression toward the mean rather than due to a treatment variable presented between the pretest and posttest. Another threat to internal validity is subject *mortality*. Specifically, rather than the treatment variable, differential loss of subjects in two or more groups during the course of a study may be responsible, in some instances, for a between-groups difference on a dependent variable.

Common Designs

In most cases the primary reason a design is categorized as a preexperimental design is because it lacks a control group. Yet in spite of the limitations associated with a preexperimental design, an educational researcher may occasionally employ such a design because ethical or other considerations may make it impossible or impractical to use a quasi- or true experimental design. A quasi-experimental design is more likely to be employed in educational research than is a preexperimental design, even though the internal validity of such a design is also compromised. In most instances, lack of random assignment is responsible for compromising the internal validity of a quasi-experimental design. Because many education-related issues are difficult to study through use of a true experimental design, a researcher may have no choice but to use a quasi-experimental design to investigate a hypothesis of interest. Typically, such designs will contrast the performance of two or more intact groups, such as students in different classes or towns. Use of preexisting groups in the latter type of situations does not allow a researcher to assume equivalence, as there is no reason to believe the different groups represent random samples.

A hypothetical study will be described that represents an example of a *nonequivalent control group design*, which is one type of quasi-experimental design. Assume two classes of 100 students in the same school are taught mathematics at approximately the same time of day by the same teacher. One class is taught by a method to be identified as Method A, whereas the other class is taught by a different method, to be identified as Method B. At the beginning of the school year, students in both classes are administered a standardized math achievement test that will represent a pretest measure of the dependent variable. The different teaching method each class is exposed to will represent the independent variable. At the conclusion of the school year, both classes are administered a posttest on the dependent variable. A determination with respect to whether one teaching method is superior to the other is based on the difference between the pre- and posttest scores of the two classes. At the conclusion of the study, a change score is computed for each student by computing the difference between a student's pretest and posttest scores (it will be assumed that both classes exhibit superior performance on the posttest). If the mean change score of students in the class that was taught by Method A is significantly greater than the mean change score of students who were taught by Method B, one might be tempted to conclude that Method A is superior to Method B. The latter conclusion, however, could be challenged by virtue of the fact that students were not randomly assigned to the two classes. For instance, there is the possibility that during the school year, the students in the class taught by Method A were more likely to have been exposed to conditions outside of the classroom that were conducive to increasing their skills in mathematics. If, on the other hand, students had been randomly assigned to the two classes at the beginning of the year, the likelihood of the latter would be minimal, and consequently, the design of the experiment would then conform to the requirements of a true experimental design. More specifically, use of random assignment would transform the design into a *pretest-posttest control group design*, which is one type of a true experimental design.

Another example of a quasi-experimental design is a *time-series design*, in which *multiple measures* are

obtained on a dependent variable before and after an experimental treatment. One type of time-series design is the *multiple time-series design* in which multiple measures on a dependent variable are obtained for two intact groups (i.e., groups that are formed on the basis of nonrandom assignment) before and after one of the groups is exposed to some intervention. For example, academic achievement scores might be obtained for a cohort of students for each year during a period 5 years before and 5 years after the introduction of a new curriculum in a school district. The latter scores are then compared over the same time period with the scores of what is considered to be a comparable cohort of students in another school district that did not implement the change in curriculum.

Another type of design that is often categorized as a time-series design is a *single-subject design.* This design is commonly employed with a single individual in order to demonstrate the efficacy of a behavior modification procedure on some form of maladaptive behavior. For example, in an *ABAB* design, a baseline measure of the maladaptive behavior is obtained during the initial time period, labeled A. During the second time period, labeled B, the treatment is administered and if successful, there will be a decrease in the frequency of the behavior. To confirm the treatment was responsible for the decrease in the behavior during time B, it is withdrawn during the third time period, labeled A. During the final time period, labeled B, the treatment is reintroduced in order to permanently eliminate the maladaptive behavior.

Although not categorized as time-series designs, *longitudinal* and *cross-sectional* designs are also employed in educational research to evaluate subjects' behavior over a prolonged period of time. The longitudinal design typically involves a large cohort of subjects who are repeatedly evaluated in order to determine whether or not change occurs with respect to a variable of interest with the passage of time. As an example, to determine whether or not intelligence changes during the course of one's lifetime, a cohort of individuals may be administered an intelligence test every 10 years. The same question can also be addressed through use of the cross-sectional design, which evaluates multiple cohorts comprising subjects of different age levels with respect to the variable of interest. For example, a researcher might compare the scores on an intelligence test of cohorts comprising individuals who are 10, 20, 30, 40, 50, and 60 years

of age. Because nonrandom subject mortality and historical variables can compromise the internal validity of longitudinal and cross-sectional designs, respectively, neither conforms to the requirement of a true experimental design.

A common distinction in designing an experiment is that between an *independent* and *dependent samples design.* In an independent samples design, each group comprises different subjects, whereas in a dependent samples design, the same subjects are exposed to all of the experimental treatments. A dependent samples design can also involve *matching* or *blocking* subjects. Matching subjects requires that a researcher initially identify one or more variables that are positively correlated with the dependent variable. Such a variable is referred to as a matching variable. To illustrate, consider an experiment composed of two experimental conditions in which a researcher stipulates that 10 subjects will serve in each condition. To match subjects, the researcher initially selects 10 subjects to serve in Condition 1. The researcher then identifies 10 different subjects to serve in Condition 2, with the stipulation that each subject in Condition 2 is comparable to one of the subjects in Condition 1 with respect to the matching variable (e.g., intelligence). The latter study, which will comprise 10 pairs or *blocks* of subjects, is evaluated as a dependent samples design. Although a dependent samples design is more sensitive than an independent samples design in identifying treatment differences, it is less commonly employed due to the practical problems associated with employing subjects in two or more conditions or in matching subjects.

The design of an experiment can be considerably more complex than what has been described up to this point. An example of a more complex design commonly employed in psychological research is the *factorial design*, which is able to simultaneously evaluate the impact of two or more independent variables on one or more dependent variables. A major advantage of the factorial design is it allows the researcher to identify an interaction between variables. An *interaction* is present when subjects' performance on one independent variable is not consistent across all the levels of another independent variable.

EXPERT TEACHERS

A number of forces concerning educational policy have come together to raise the awareness and research concerns over the identification and preparation of *expert teachers* for America's school systems. Criteria for identifying expert teachers are being identified and studied from different perspectives, including those of teachers, principals, and students, and then examined closely as these research findings are applied to the preparation of future teachers and the induction of beginning teachers into the schools.

No Child Left Behind

There are two major components of the No Child Left Behind (NCLB) legislation that dominate current discussions related to K–12 education. The first is the closing of the achievement gap between groups of students, by focusing on standardized achievement tests of student knowledge and skills each year to provide an index of adequate yearly progress (AYP) for students in U.S. schools. The repercussions of failure to make AYP are severe and have dramatically changed curricula and teaching practices as teachers and administrators focus on preparing students to succeed in the local testing setting that varies state to state.

In 2001, President George W. Bush enacted NCLB legislation, which reauthorizes the Elementary and Secondary Education Act of 1965. These reforms were intended to increase accountability for states, school

districts, and schools; provide greater choice for parents and students; give more flexibility to states and local educational agencies in the use of federal education dollars; and put forth a greater emphasis on evidence-based teaching methods that increase student academic achievement (Executive Summary). To meet many of these intents, NCLB calls for an increase in the number of highly qualified teachers in the classroom (Section 2101). Whereas much debate in the literature exists about the definition of highly qualified teachers (also referred to as excellent teachers, effective teachers, and expert teachers), according to the NCLB legislation, a highly qualified teacher

- holds a bachelor's degree;
- is certified or licensed in his or her state;
- has demonstrated subject matter competence, as defined by the state in each of the core academic subjects he or she teaches; or
- does not have certification or licensure requirements [because they were] waived on an emergency, temporary, or provisional basis (Section 1901).

Defining Expert Teachers

Aside from the NCLB definition of expert teachers, many researchers have attempted to define the qualities of excellent teaching. In addition to determining the attributes of excellent teachers, researchers have examined the extent to which preparation helps teachers become excellent teachers as measured by student achievement. For instance, researchers have found that content preparation is positively related to student achievement in a curvilinear manner in which a threshold exists beyond which preparation is not significant in predicting student achievement. However, other research has indicated that for higher-level courses (usually in high schools), the amount of content training a teacher has had becomes very important. Although teachers often are required to be tested by their state to indicate competency, studies have reported more frequently that course-taking is a better indicator of teacher excellence than are teachers' test scores alone. This is probably because teacher assessments have not been adequately designed to accurately gather authentic measures of critical thinking, problem representation, pedagogy, and actual teaching practices.

The debate regarding the assessment of teacher effectiveness is whether coursework in education is more important than subject-matter coursework

completed in arts and sciences and related areas. Several studies have demonstrated that, indeed, education courses are more critical to teaching than are subject-matter courses. A different perspective places value on both pedagogical knowledge, as gained from education courses, and subject-matter knowledge where an interaction between the two exists. Finally, at the other end of the continuum are studies that have found that students demonstrate greater achievement when taught by teachers who are certified in their field, who have earned a master's degree, or who are enrolled in graduate courses. However, when examining this research, it is important to remember that the schools in which students are often failing are the schools in low-income neighborhoods where multiple languages are spoken and where a larger proportion of teachers are less qualified, less experienced, and more often teaching out of their certification area. As research has shown, many qualified teachers teach in schools where students are from a higher socioeconomic status. Thus, when examining teacher effectiveness, one must account for the complex relationship between teacher qualification and experience and student socioeconomic status.

The argument that effective teachers are those who are certified in their field, have a master's degree, or are enrolled in graduate studies follows the line of research about experts in general. Literature on experts indicates that experts have more domain-specific knowledge, the ability to form more accurate and better problem representations, the capacity to recognize problem-types, and the skill to be forward-working and top-down processors. Moreover, the research on expertise demonstrates that experts self-regulate and, as a result, are more flexible and can change representations faster. They also impose automaticity of lower-level cognitive processes, which frees memory capacity for more complex information. Finally, experts are experts in a specific domain; they are not experts in everything.

Researchers in the field indicate that defining an excellent teacher is difficult for a number of reasons. First, unlike fields with competitions or tournaments that identify an expert (e.g., chess and bridge), there exists no such process in education. The closest objective measurement is student performance on standardized achievement tests. Yet, this measurement of expertise is confounded by the entry characteristics of the students when the teacher receives the students assigned to him or her, not to mention the issue of

socioeconomic status and other factors confounded with test scores.

National Board-Certified Teachers

A close approximation to an objective measurement of teacher expertise is board certification, created by the National Board of Professional Teacher Standards (NBPTS). Research from this elaborate and multifaceted process found that there were 13 prototypical features of expert teachers. The features are as follows:

1. Better use of knowledge
2. Extensive pedagogical content knowledge, including deep representations of subject-matter knowledge
3. Better problem-solving strategies
4. Better adaptation and modification of goals for diverse learners and better skills for improvisation
5. Better decision making
6. More challenging objectives
7. Better classroom climate
8. Better perception of classroom events and better ability to read the cues from students
9. Greater sensitivity to context
10. Better monitoring of learning and providing feedback to students
11. More frequent testing of hypotheses
12. Greater respect for students
13. Display of more passion for teaching

These NBPTS attributes of expert teachers are consistent with the attributes of expert teachers identified by researchers in the field.

A Qualified Teacher in Every Classroom

According to NCLB regulations, the subject-matter competence for elementary teachers is defined by a state test of the basic elementary school curriculum and the state's high, objective, uniform, state standard of evaluation (HOUSSE). Secondary teachers responsible for core academic subjects, such as English, reading or language arts, mathematics, science, history, civics and government, geography, economics, the

arts, and foreign languages, must demonstrate competence in the content area(s) they are teaching. For secondary teachers, subject-matter competence must be met in each core academic subject they teach. This can be met by passing a state test in each subject or by completing an academic major, graduate degree, coursework equivalent to an undergraduate degree, or advanced certification. This competence can also be met by completing the state's HOUSSE in that subject.

The criteria for the HOUSSE (see the NCLB Toolkit)

- are set by the state for grade-appropriate academic subject-matter knowledge and teaching skills;
- are aligned with challenging state academic content standards and student achievement standards and developed in consultation with core content specialists, teachers, principals, and school administrators;
- must provide objective, coherent information about the teacher's attainment of core content knowledge in the academic subjects in which a teacher teaches;
- are applied uniformly to all teachers in the same academic subject and the same grade level throughout the state;
- take into consideration, but are not based primarily on, the time a teacher has been teaching the academic subject; and
- are made available to the public upon request.

Beyond Pedagogy

Beyond general pedagogical knowledge and pedagogical content knowledge, other characteristics have been deemed important in excellent teaching. For instance, studies of the many kinds of knowledge attributed to teachers' effectiveness have revealed the following qualities and qualifications: general academic and verbal ability, subject-matter knowledge, knowledge about teaching and learning, teaching experience, and the set of qualifications measured by teacher certification in addition to traits such as enthusiasm, perseverance, flexibility, and concern for children. Studies also show that effective primary teachers utilize more engaging activities, demonstrate greater enthusiasm about the subject matter, hold higher expectations, praise student achievements, and encourage self-regulation. Studies have also found that being child-centered, being able to motivate students, showing empathy, and demonstrating consistency could increase the success of teachers.

Quantitative Definitions to Expertise in Teaching

Two quantitative approaches have been used to identify and define expertise in teaching. *Value-added modeling* is based on a statistical procedure that was used to analyze data related to the characteristics of a group of Tennessee teachers who consistently demonstrated student learning.

Growth curve modeling employs a regression analysis to predict student learning over three points in time and then compares predicted student achievement levels with actual student achievement. Those teachers who produced higher levels of student achievement than predicted were examined for characteristics that contributed to expertise in teaching, as measured by student achievement.

Both of these approaches are valuable tools researchers can use to examine patterns of teacher expertise while also attempting to account for student characteristics.

Elementary and Secondary Expert Teachers

Researchers have also distinguished between expert teachers in the elementary versus secondary grades because of the inherent differences between the structures of many of these typical classrooms. Specifically, teachers in the elementary grades are often responsible for the total curriculum, except for special areas such as music, art, and physical education. On the other hand, a secondary teacher may be responsible only for a specific content area although there may be different courses assigned within one general area, such as mathematics, algebra, and geometry. Teachers at the primary level may be teaching a group of 25 students for the entire day, whereas secondary teachers may be teaching five different classes of 25 students a day. Differences in classroom management, discipline as well as transitioning from one topic to another, will vary with the age of the students and the content areas. Relationships between the teacher and the students will also vary due to the time together in the classroom and the nature of the relationships developed. Although there are clear differences in the issues faced by teachers of second versus tenth graders, there are also common elements of successful teaching practices shared across these two different settings.

The Teachers for a New Era Initiative

In 2001 the Carnegie Corporation, along with additional funding from the Annenberg and Ford foundations, launched the Teachers for a New Era (TNE) initiative, which focused on the preparation of excellent teachers based on three fundamental design principles: evidence-based decision making, the engagement of arts and sciences faculty in the preparation of teachers, and the preparation of teachers through clinical practice and a systematic induction process for beginning teachers in their first teaching assignments.

Eleven colleges and universities across the United States were funded to follow these three principles and provide evidence of the development of excellent teacher preparation programs to be replicated and extended. The criteria for demonstrating the preparation of expert teachers is demonstrable pupil learning, that is, the evidence that the teacher has consistently demonstrated that his or her students learn, as measured by a valid and reliable measure of academic achievement. Although this national initiative holds great promise for establishing further evidence on the preparation of expert teachers, as measured by their impact on their students' learning, it is too early to judge. Changes in curriculum in preparing teachers were initiated only several years ago and the effects of these changes will not be available until these new teachers of TNE programs have completed their training and been given ample time to refine their knowledge, skills, and dispositions as they directly influence student learning for several more years. However, this initiative holds great promise because of the consistency of the application of the design principles and the focus on demonstrable pupil learning as the criteria for determining expertise in teaching.

International Perspectives

Studies have indicated that definitions of excellent teaching have been problematic because excellent teaching is contextually and culturally defined. For instance, in the United States, participatory learning is considered a strategy of excellent learning. In China, however, where students are deferent to their teachers, participatory learning is considered to be disrespectful. Additionally, in some countries, such as Taiwan, where texts are selected and teachers are given one national curriculum, teachers' expertise in teaching and learning is very difficult to measure or evaluate. Similarly, several studies have pointed out that excellent teachers in urban schools must possess domain knowledge in urban culture, urban political economy, community, and social service support networks.

Expert Teachers at the College Level

While student performance in high-stakes testing often determines the effectiveness of teachers at the K–12 level, student ratings have a significant impact on the evaluation of teachers and their effectiveness in higher education. For numerous years, students have been asked to identify characteristics of effective teachers. Effective teachers at the college level have been studied since the 1950s, and the characteristics have differed minimally. One study found that five characteristics of effective teachers were frequently cited as follows: capture students' attention, stress important material, make good use of examples and illustrations, inspire class confidence in their knowledge of the subject, and provide clear explanations. Another study of undergraduates indicated that a thorough knowledge of content matter, as well as preparedness, organization, enthusiasm, and student-orientedness, were critical in teaching expertise.

EXPLICIT MEMORY

Explicit memory refers to the consciously mediated, deliberate attempt to retrieve a memory from the past. Explicit memory is critically important in educational psychology because the most conceptual learning by students and testing of knowledge by teachers engage explicit memory encoding and retrieval processes. In this entry, the major factors influencing explicit memory that are educationally relevant are reviewed, followed by a description of the educational implications of explicit memory processes.

Factors Affecting Explicit Memory

Explicit memory is generally measured by one of two types of memory tasks: *recognition* or *recall*. Common classroom recognition tasks are multiple-choice and true-false questions; common classroom recall tasks are fill-in-the-blank questions and essays. In general, both recognition and recall are enhanced more by encoding processes that focus on concepts and meaning than they are by encoding processes that focus on perceptual attributes of information. Furthermore, both recognition and recall are affected more by manipulations that influence the amount and type of concept-based processing people perform than by manipulations that influence the amount and type of perceptual processing people perform. Together, these two facts suggest that explicit memory is most effectively enhanced when people attend to the conceptual aspects of information.

A second consideration for understanding explicit memory in the context of education is how information is studied. Two phenomena, the *spacing effect* and the *testing effect*, are particularly important. The spacing effect refers to the finding that distributing repetitions of information over time by placing other events in between the repetitions yields considerably better memory performance than repeating the same item twice in succession. The testing effect refers to the finding that people's memory improves most when they interleave memory retrieval attempts with the study of information. Thus, alternating between studying and retrieving produces faster learning of information immediately and dramatically better retention over time compared with repeated study of information with only intermittent retrieval.

Finally, there are differences between recognition and recall retrieval processes. Recognition memory tends to be strongly influenced by the alternatives that are presented along with a correct answer. Thus, if the incorrect alternatives on a recognition memory test are very similar to the correct answer, accurate recognition will require a more precise memory than if the incorrect alternatives are dissimilar to the correct answer. Recall, on the other hand, tends to be thought of as a process whereby a person uses cues he or she is given, such as a question or concept, to search for potential answers in their memory.

One perspective that provides a useful framework for thinking about the process of recall distinguishes between similarities and differences among memories. Similarity among memory traces, such as being from the same conceptual category (e.g., fruits), is useful for searching through memory in an effort to find candidate responses. Once a candidate response is located, it is useful to have information in a memory trace that distinguishes it from other traces that are similar and therefore also possible responses. In essence, difference information helps identify a candidate memory as the exact trace a person was attempting to retrieve.

Educational Implications

The features of explicit memory reviewed in this entry have implications for instructional techniques, students' study techniques, and testing. Regarding instruction, it is generally beneficial to use classroom instruction to inspire students to process information meaningfully, such that they can access their existing knowledge base and integrate newly learned information with their existing knowledge. This will allow them to notice commonalities between new concepts and their

existing knowledge base. However, it will also be useful for classroom instruction to note features that distinguish a new concept from existing concepts. Together, these two factors import the role of similarity and difference in explicit memory retrieval into the educational context, enabling improved access to new information, as well as improved ability to determine when the new information is (and is not) appropriately applied. Furthermore, it is useful to review at periodic intervals or to recommend that students take it upon themselves to review concepts at regular intervals. This takes advantage of the spacing effect, which promotes improved long-term remembering by distributing repetitions of information over time and intervening events. Third, students should be instructed to test themselves as they study. This recommendation makes use of the testing effect, where interleaved study and retrieval have been shown to promote improved retention compared with repeated studying with little testing.

Finally, the method of testing used has implications for the kinds of knowledge students may be able to assess. The instruction and study recommendations noted in this entry are largely tailored to improving recall performance (essay, fill-in-the-blank), although they will also tend to be effective at improving recognition memory performance (multiple-choice, true-false). If the assessment used is a multiple-choice test, it is important for educators to be aware of the sensitivity of recognition memory to incorrect response alternatives. In particular, if only one response alternative on a multiple-choice question is plausible or was encountered in the classroom curriculum, students will be able to answer that question accurately based on the fact that only one possible answer contains a concept that they encountered in the classroom. On the other hand, if multiple response options are plausible and were encountered in the classroom context, students will need to possess more precise knowledge of class concepts to answer that question accurately. In essence, increasing the similarity between the incorrect test alternatives and the correct answer on a multiple-choice test should allow instructors to evaluate the specificity and precision of students' knowledge of subject matter, as opposed to simply assessing whether or not they have encountered a concept in the classroom context.

EXPLICIT TEACHING

The term *explicit teaching* refers to a method of instruction in which the teacher, who serves as a provider of knowledge, presents skills and concepts in a clear, systematic, and direct way that promotes student mastery. *Explicit teaching* refers to the type of direct, teacher-led instructional explanation a teacher employs when describing curricular content and procedures, strategy instructions, skills and concepts, and rules for memorization through verbally detailed explanations and examples. Explanations may include the teacher modeling a skill or concept, followed by the teacher guiding and providing feedback as the student practices applying the skill or concept. Students are provided many opportunities to apply, independently, the skill or concept so as to ensure their mastery and generalization of the skill. Explicit teaching methods include the teacher reviewing previous material, describing procedures, highlighting, modeling skills using cues and prompts, questioning students directly to ensure understanding, providing feedback and progress monitoring while presenting multiple opportunities for students to practice the skill to mastery, and providing opportunities for students to apply the new skill. During the modeling process, the teacher uses "think-alouds"; that is, the teacher talks aloud about what he or she is thinking. The teacher provides specific examples of the sequence broken into small steps and the mental processes that occur as the teacher thinks aloud through the procedure, thereby modeling the incremental mental steps for the student. Think-alouds provide the student with detailed sequential step-by-step information which the student uses as an example when he or she goes through the mental process of solving the problem. Explicit teaching prevents confusion on the part of the student by always describing each step and by not assuming that a student should be able to

combine steps. Explicit explanations assist the student in knowing how and when to use the skill or concept. To retain student attention and focus, instructional procedures are presented at a brisk pace.

Explicit teaching is appropriate when the student must demonstrate a high level of mastery of a task-specific strategy, when student acquisition of skills or factual content is essential before further skills or concepts can be acquired, when the student has little or no background knowledge of concepts, or when the student experienced initial failure with content. When the complexity of the task is reduced by breaking the procedure into smaller steps, student mastery improves. With small specific steps, opportunities for student error are reduced. An explicit approach is appropriate when limited time is available, mastery is essential, or the task is complex or potentially hazardous.

Reading and Mathematics Instruction

Explicit teaching can be used for teaching reading strategies, such as mastering phonemic awareness. Later, explicit teaching ensures that the student is identifying words correctly. As the student practices, the teacher can confirm that the student is practicing the skill correctly through frequent monitoring and questioning. Daily practice of automatic decoding and reading fluency ensures a high level of student proficiency by allowing the student to shift attention from decoding to comprehension. Comprehension concepts, such as cause and effect, reality and fantasy, and literal and inferential questions, can be taught using explicit instruction.

Explicit teaching focuses on student mastery and teaching subskills sequentially, usually through small group instruction. In mathematics, explicit teaching is used to demonstrate performing steps in algorithms. The teacher describes aloud what he or she is thinking at each step. The teacher leaves a completed model with the student as a referent for cuing purposes. Imitating the teacher's process, students try solving similar problems. The teacher, monitoring the student's repeated practice, ensures a mastery level of basic mathematics facts fluency and of operational procedures by the student.

At-Risk Students

Explicit teaching is effective for helping low-performing students acquire reading, spelling, and mathematics skills. Students at risk for school failure, with learning disabilities or other special needs, or with limited experience or proficiency with lesson content are most successful when taught through explicit instruction with educators maintaining a brisk lesson pace, fostering high student accuracy, and prompting students rather than telling them correct answers.

Procedure for Explicit Teaching

Explicit teaching provides a clear statement and prevents vagueness and ambiguity, thus increasing the likelihood of understanding by the student. Using explicit teaching, the teacher

1. states the goals of the lesson;

2. reviews previous learning whose mastery is a prerequisite to learning the new skill or concept;

3. presents new material in small steps with clear, detailed, sequential step-by-step instructions and explanations;

4. models each step by physically demonstrating the directions and verbally describing the mental processes;

5. provides active student practice until each step is mastered;

6. guides, monitors, and provides systematic feedback during students' initial practice;

7. checks for student understanding through detailed questioning;

8. provides students with high levels of successful independent practice until mastery level is obtained;

9. provides students with opportunities for skill application; and

10. continues weekly and monthly reviews to ascertain students' sustainability of mastery level of skill.

The emphasis of explicit teaching is on student mastery. The pedagogical processes (i.e., modeling, highlighting, feedback, review, practice, and application) provide the teacher with many opportunities to check on skill mastery by the student. The principles of explicit teaching are inherent in direct instruction, effective teaching practices, exogenous constructivism, and behavioral theory.

EXTERNAL VALIDITY

External validity refers to the ability to generalize the findings of an experiment to other settings, populations, and times. For educational psychology, this ability is a vital one, because it indicates the extent to which various programs shown to improve learning in one (perhaps artificial) setting can be confidently expected to show similar improvements in other (real) classroom settings. Without high external validity, the program may not have its intended or presumed effect in the various populations of interest. This entry will describe external validity in detail, offer suggestions for increasing it, describe threats to it, and discuss the trade-off between external validity and internal validity.

When a new educational technique or program is being evaluated in an experimental trial, of necessity the evaluation involves, for example, a specific school or district or set of classrooms. In addition, it takes place with specific children, teachers, materials, and at a particular time. However, researchers and educators clearly do not wish to restrict their conclusions to those particular schools, teachers, children, and so on; they prefer to *generalize*, that is, assume that their conclusions about the program extends to other (or even any) schools, teachers, children, and the like. The issue of external validity concerns whether such a generalization is defensible and true.

Logically, such a generalization is hardly ever completely justifiable. Even if the experiment is later replicated in many classrooms or schools, and the same result is found, it remains logically possible that the next school will find different results. Although such an outcome always remains a logical possibility, its plausibility is related to the external validity features of the experiment.

Increasing External Validity

One approach to increasing a study's external validity is to ensure that it is conducted under conditions that are both realistic and similar to those in which the program will later be used. A more demanding approach is to use several exemplars (e.g., schools, districts) that differ in numerous ways in the initial or subsequent studies and observe whether the results replicate. The most demanding approach to achieving high external validity is to randomly select a relatively large number of exemplars from among those to which the results are hoped to eventually generalize. Under such a circumstance, schools or districts might be included as a random factor in the statistical analysis, which allows a statistical basis for generalizing.

External validity information is also often available after the study has concluded and the results have been analyzed. Subgroup analyses may indicate, for instance, that only girls' learning was increased by a specific mode of teaching and that the teaching mode had no impact on boys' learning. Consequently, the effects of the teaching mode on learning cannot be generalized across gender, because the effect is only present for girls and not boys. Many experiments are specifically designed to probe external validity by examining a previously evaluated treatment program with a new population, to establish if the program is effective with that new population and thus determine the limits of generality of the treatment effect.

Threats to External Validity

Because the experiment needs to deal with specific schools, teachers, or students, any specific element of it might be shown by later research to limit or threaten external validity. However, theorists have identified three such threats that are common across a wide range of studies. One is the interaction between selection and treatment, which refers to the possibility that those who choose to participate in the experiment differ from those who choose not to participate in ways that might cause the results to differ. For example, voluntary programs that take a considerable amount of time might elicit participation only from highly motivated or needy individuals; the same results might not have been found

with less motivated or needy participants. This challenge can be avoided, in part, if participation in the experiment is made as convenient and easy as possible. Another threat to external validity is that of the setting by treatment interaction. An experimental effect observed in a classroom on a college campus may or may not generalize to a workplace setting or to a social function. Thus, the effect of the treatment may depend upon the setting in which the experiment is conducted. This concern can be alleviated by conducting the experiment in multiple settings, to determine what, if any, impact the setting has on the effectiveness of the treatment. Finally, a third threat to validity involves the interaction between history and treatment. An effect observed in an experiment conducted immediately after the September 11, 2001, terrorist attacks may not have had the same potency 5 years later. However, this threat can be diminished by conducting the experiment again, to see if the relationship still holds, or by critically examining other evidence that may support the effect.

Trade-Offs Between Internal and External Validity

In practice, external validity may frequently work in opposition to internal validity, the extent to which the conclusion that it was a specific program that altered a certain outcome, as opposed to alternative causes of that outcome, approximates truth. This is because internal validity increases as control increases, especially control over these potential alternative causes, whereas external validity increases as variability, the antithesis of control or constancy, increases. Thus, more artificiality and purity of execution tend to rule out alternative explanations, but at the same time they compromise generality and realism. Although increasing internal validity often comes at the price of limited external validity, some experimental research designs are better than others at maximizing both. For example, the pretest-posttest control group design is highly internally valid, but the necessity of assessing outcomes twice may be highly artificial, compromising external validity. Designs that are relatively high on both include the posttest only control group design; many quasi-experimental designs, such as the interrupted time series and switching replications designs; and the combined modified design, for assessing palatability of interventions simultaneously with their efficacy.

EXTRACURRICULAR ACTIVITIES

Extracurricular activities encompass a broad range of organized adult-sanctioned activities that fall outside the scope of the regular curriculum and usually occur during the after-school hours. They can be sponsored by either the school or the community, though most research has focused on school-based extracurricular contexts. They include such diverse contexts as sports, drama, student government, math clubs, and service activities. Despite the differences in focus, extracurricular activities share several common features. They are generally voluntary, have a regular participation schedule, are supervised by adults, include other participants, involve some structure and rules, are organized around particular competencies, and include activities that require sustained attention, opportunities for meaningful participation, and clear feedback. This entry describes why the study of extracurricular activities is important to educational psychology, different ways to define and measure activity participation, effects of extracurricular involvement, and challenges researchers face in studying these contexts.

Importance to Educational Psychology

Extracurricular activities are an integral part of the school experience for many youth. In the 1999 National Survey of America's Families, 81% of 6- to

11-year-olds and 83% of 12- to 17-year-olds reported participating in an at least one extracurricular context over the past year, with sports being the most common activity. However, although a large percentage of youth participate in extracurricular activities, many still spend a great deal of time unsupervised during the after-school hours. In fact, 40% to 50% of young people's waking time is spent in discretionary activities. In a recent national study, on average, youth reported spending 5 hours each week participating in organized activities. At any one time, around 40% of youth were not involved in any organized activities. Most youth reported spending significantly more time in unstructured leisure activities, such as hanging out with friends or watching television, than they spent in organized activity contexts.

Another reason for the interest in extracurricular activities is the potential role of such activities in promoting achievement and preventing school disengagement. Conventional wisdom holds that by participating in extracurricular activities, individuals learn skills that will help them achieve in school, for example, a strong work ethic, respect for authority, time management, and perseverance. Participation also may have academic benefits because some types of activities are structured to reinforce classroom learning and offer students the opportunity to apply academic skills in real-world contexts. Involvement in extracurricular activities may be especially important for youth who do not excel academically, offering the individual another setting to develop skills and gain recognition. Participation in extracurricular activities also may enhance students' attachment to school and reduce the likelihood of their dropping out by contributing to their sense of being a valued member of the school community. Finally, spending time in these settings may have motivational benefits. Youth report high rates of alienation and boredom in traditional curricular contexts but positive affect and motivation in organized out-of-school activities.

Demographic changes also have fueled the interest in research on the effects of extracurricular participation. An increase in parents' work commitment has resulted in large numbers of youth who are unsupervised during the after-school hours. Research has shown that the lack of adult supervision places these children at a higher risk for negative outcomes. High rates of family mobility and the disorganization of many neighborhoods have also weakened the informal supports for many youth. Participation in organized programs, like extracurricular activities, during the after-school hours can help to compensate for the absence of family and community supports.

Effects of Participation

Researchers in such diverse areas as leisure studies, sociology, sports psychology, and adolescent development have explored the effects of extracurricular involvement. Converging evidence from these literatures generally supports the hypothesis that participation has beneficial effects. There is a more extensive literature on sports than on other activity contexts, though more recent research has begun to take a nuanced approach and examine developmental outcomes across a range of activities. This research has helped to illustrate which findings are unique to sports and which findings hold more broadly across a range of activity contexts.

Much of the research has focused on the academic effects of extracurricular involvement. Several studies have linked activity participation to grades, test scores, school engagement, attendance, and educational attainment. Other work has shown a correlation between participation and indicators of psychological adjustment. For instance, extracurricular participation is related to higher self-concept and interpersonal competence and lower rates of depression and anxiety. Involvement in high school extracurricular activities also appears to have some beneficial effects for adult development, including a higher likelihood of college attendance, more favorable mental health outcomes, and increased involvement in political and civic causes. Finally, extracurricular involvement is associated with a reduction in problem behavior. For example, participation predicts staying in school, lower rates of delinquency, and lower rates of substance use. The protective benefits seem to be largest for high-risk youth.

Although most of the effects are positive, there is evidence of some potential costs to participation in certain types of activities. For example, some studies find that sports participation is related to higher levels of alcohol use. One explanation for this finding is that drinking is a part of the culture of athletics and is supported and reinforced by other peers. Another concern is the inappropriate behavior of some parents and coaches in youth sports. The potential for negative peer group dynamics, especially in less structured extracurricular contexts, also has been highlighted. Finally, some have expressed concern over the competition and the stress associated with excessive

involvement in extracurricular activities, especially among upper-middle-class families.

Explanations for Benefits

The primary goal of most studies has been to correlate extracurricular participation with individual-level outcomes. Although these studies provide evidence of the beneficial effects of activity involvement, these predictive findings provide little information about the reasons for these associations. A few scholars have begun to explore the characteristics of activity contexts that may help to explain the effects of extracurricular participation, though this research is clearly in its infancy. One explanation is that participation in extracurricular activities links adolescents to a set of similar peers. These peer groups develop an activity-based culture with shared norms and values. Participation in extracurricular activities also affords youth the opportunity to form close bonds with caring, nonfamilial adults outside of the classroom who can provide them with support, mentorship, and advice. Another explanation for the possible benefits of participation is that in these contexts, youth can explore their identity by trying new activities and clarifying their values and interests. Participating in organized activities also may help to foster initiative, or self-directed action, because these are contexts in which youth experience high motivation, challenge, and attention. Finally, the benefits of extracurricular involvement may be explained by the fact that youth can develop social, emotional, and psychological competencies that may transfer into other domains of their lives.

Student Characteristics and Extracurricular Participation

The extent to which extracurricular participation has an impact on the outcomes of development varies as a function of individual factors, such as gender, age, and ability. With the exception of sports, girls are more likely to report participating in all other types of extracurricular activities than are boys. Another common finding is the decline in participation in many organized activities as children move through adolescence. In the later grades, there are fewer slots and increasing competition for positions in many activities. The decline also likely reflects competing demands for time from school, peers, and work. An individual's ability level also affects participation.

Many schools have policies requiring students to maintain a minimum grade point average to participate in extracurricular activities. In addition, membership in some types of activities, such as music and sports, is determined by skill level.

Contextual factors also shape extracurricular participation. Access to extracurricular activities varies depending on school and neighborhood factors. In low-income communities, there are fewer resources, like athletic fields and community centers, to support extracurricular participation. In contrast, in some upwardly mobile communities, there are concerns about the overinvolvement of youth in school and community-based extracurricular activities. Parents desire to enroll their children in extracurricular activities, and their ability to manage this involvement also varies depending on time, economic resources, and their beliefs about the value of this participation.

Measuring Extracurricular Participation

The relation between extracurricular participation and development is likely to vary as a function of the type of activity, frequency of participation, breadth, and duration of involvement. A common method for assessing involvement is to ask individuals to check off on a survey whether they had participated in different activities (yes or no) and aggregate these items into a single composite measure. One assumption underlying this measurement strategy is that all activities are similar. However, the reality is that extracurricular activities offer different affordances for developing skills and relationships with adults and peers. For example, an activity like sports takes place several times a week, involves competition, is closely supervised by a coach, and has extensive opportunities for social interaction. In contrast, an activity like a foreign language club takes place less frequently, involves fewer opportunities for social interaction, and has less contact with an adult leader. Few studies have examined qualitative differences in the nature of participation across a wide range of activities, making it difficult to identify both the commonality and diversity of developmental experiences youth encounter in extracurricular activities.

Other studies have examined the relation between the total number or total time in extracurricular activities and development. This research has been guided by a zero sum model of time involvement. Greater

participation in extracurricular activities is assumed to negatively influence achievement because time spent in these activities takes away from time that can be spent on academics. A similar concern has been raised in popular media reports about overscheduled adolescents and the negative consequences for family functioning and youth well-being. A few studies have found a curvilinear relationship between activity participation and development. This work suggests that there is a threshold in which the number of activities no longer exerts positive influence on developmental outcomes. However, in contrast to the media reports of the stressed-out and overscheduled adolescent, the majority of research has shown that more participation is beneficial. More time in organization activities is likely linked to less time in either unsupervised risky activities or unproductive activities, both of which have been associated with less positive outcomes. In fact, evidence from a recent national sample of youth, shows that only a small percentage of youth (3%–6%) spend considerable time on organized activities; most youth report spending the majority of their leisure time in unstructured activities.

Another important question concerns differential associations between the breadth of activity involvement, or combination of extracurricular activities, and outcomes. Surprisingly few studies have explored this question. Limited research shows that youth in a single extracurricular activity have more favorable outcomes than youth who are not involved in any organized activities, but youth who are involved in a variety of domains have the most beneficial outcomes. Participating in a range of extracurricular contexts may be related to the most positive outcomes because different activities provide different affordances for development. Finally, there are likely to be differences in outcomes depending on the intensity or duration of involvement. Skill building and fostering relationships with adults and peers take time. The few empirical studies that have examined the effects of the duration of involvement show a positive relationship between sustained activity participation and youth development.

Limitations of Research and Future Directions

There are several gaps in the literature on extracurricular activities. Although researchers have learned a lot about the predictive effects of extracurricular involvement, there is much less information on what is happening inside these activity contexts. In fact,

few studies outside of sport psychology have measured characteristics of the activity setting. This is a critical issue as both policymakers and educators ask what about these activities matters and why. Qualitative studies that explore the contextual features of different extracurricular contexts can advance the knowledge of activity settings in important ways. The field will also benefit from longitudinal studies that are designed to evaluate theoretically based hypotheses about possible explanations for the effects of extracurricular participation. Finally, experimental studies that actually test the hypotheses about mediating factors, such as relationships with adults or peer characteristics, can help to shed light on which features of the experience matter and why some extracurricular contexts are related to more favorable patterns of development than others.

In a recent review of organized community and after-school activities for youth, the National Research Council identified eight characteristics of high-quality programs that promote positive development:

1. Physical and psychological safety

2. Appropriate structure

3. Supportive relationships

4. Opportunities for belonging

5. Positive social norms

6. Support for efficacy and mattering

7. Opportunities for skill building

8. Integration of family, school, and community efforts

This list provides an important framework for how and why different extracurricular activities like sports, student government, and drama might promote positive development. However, more research is necessary to understand what each of these features look like in different extracurricular contexts, how they interact to effect development, and which features are most important for different activities and why.

Accounting for self-selection into and out of activities is another methodological challenge. Unlike most parts of the curriculum, extracurricular participation is voluntary. As a consequence, individuals who choose to participate are often fundamentally different from youth who are not involved. Participants tend to be of higher socioeconomic status, academic ability, and have more parental support than nonparticipants. Because these factors also predict positive developmental outcomes,

failing to adjust for self-selection into activities likely overstates the benefits of extracurricular participation. In fact, in studies that have adjusted for self-selection, the strength of the relationship between extracurricular participation and developmental outcomes is reduced and, in some cases, is no longer significant.

Although there is some research on why youth select themselves into extracurricular activities, few studies have examined the factors that explain why they maintain this involvement over time. The field will benefit from longitudinal studies that begin before children start participating in extracurricular activities and track their development through adolescence and into adulthood. Person-environment fit models represent one framework for understanding why some individuals continue to participate in extracurricular activities and others drop out, especially during adolescence. Initially, youth choose to participate in activities that match their interests and talents. They will be more likely to remain in activities if the characteristics of the setting continue to match their competencies and motivation. The decline in organized activity participation during adolescence may be explained partly by the fact that some extracurricular activities fail to change to reflect the developmental needs for autonomy, respect, and belonging during this period.

Refining the measurement of extracurricular participation is another important area of future work. *Extracurricular activity* is a blanket term used to apply to any activity that is "extra" or outside of the curriculum. There has been very little discussion in the literature of the defining characteristics that are common to all extracurricular contexts, as well as the subtle and not so subtle ways organized activities differ. There are also variations in the nature of extracurricular participation in school-sponsored and community-sponsored activities, though few studies have made this distinction. Much of the previous research has focused on describing the characteristics of single activities rather than comparing organizing activities with each other or with other aspects of young people's lives (i.e., unstructured leisure, school, family, peers). This makes it difficult to disentangle whether differences in extracurricular contexts reflect the types of individuals who choose to participate in each type of activity or the characteristics of the activities themselves.

A common approach is to group different extracurricular activities together and aggregate these activities into a single item. Failing to account for differences among activities likely masks some of the effects of

extracurricular involvement on developmental outcomes. However, considering a large number of separate activities often is not realistic because of constraints of sample size. In developing measures of extracurricular participation, researchers face an ongoing tension between conceptual clarity and practical reality. The decision to use more nuanced or more global categories of extracurricular participation depends on the sample size and goals of the study. It may be more appropriate to use nuanced measures of participation when the goal is greater theoretical understanding about the characteristics of activity settings and the unique contributions of different activities to variance in outcomes of interest. However, it may not always be feasible or even practical to include such detailed measures because of the large number of survey questions and limited number of youth who participate in some extracurricular activities.

Most of the literature has focused on the effects of participation in one activity context at one point in time. However, the reality is that youth move in and out of different extracurricular activities over the course of a year and often participate in several domains at the same time. Future research should explore patterns of participation and how these different trajectories are related to indicators of adjustment. For example, research on the consequences of very high amounts of organized activity participation over time can help to inform the debate about whether involvement in extracurricular activities has become excessive for some youth. Another interesting question is what combination of extracurricular activities is associated with the most positive outcomes. Person-centered, analytic techniques can help to illustrate different configurations of activity involvement and the relation of these profiles to a range of developmental outcomes. Moreover, for many youth, participation in unstructured activities fills a much larger portion of their leisure time than participation in extracurricular contexts. Exploring the ratio of structured to unstructured activities may be one way to assess this involvement.

Another critical issue is whether the effects of extracurricular participation vary by student characteristics. To answer who benefits most from extracurricular participation, researchers need to expand the range of populations that are being investigated. More is known about extracurricular participation and development for middle-class White youth than for individuals from diverse backgrounds. Moreover, an underlying assumption guiding much of the literature is that participation has the same effect on all youth.

The effects of extracurricular participation may differ depending on the child's gender, race, socioeconomic status, risk level, and achievement, though few studies have explored this question. There also are likely to be important differences by the level of involvement and success with an activity. For example, the star of the basketball team is likely to have a different experience than a substitute who rarely plays.

Most of the previous research has examined extracurricular contexts in isolation. These activities are nested within schools and communities and are functions of the available resources and larger culture of these contexts. Ecological models assume that development is shaped by multiple overlapping spheres of influence, such as the family, school, and peer group. Examining the experience of extracurricular participation in relation to these other contexts will provide more insight into the effects of activity participation than will exploring a single domain in isolation. Extracurricular involvement may have a different effect on development depending on whether these contexts are in synchrony or conflict. An interesting question is whether a positive experience in an extracurricular context can compensate for a negative experience in another domain. Limited research suggests that high-risk and low-income youth may benefit more from extracurricular participation than other youth. This finding may reflect the fact that these youth have access to fewer of the developmental affordances in extracurricular activities in other aspects of their lives, though more research is needed to evaluate this claim. There is a need for more sophisticated research designs to identify interrelations between different contexts and examine the role of context in shaping extracurricular participation.

In conclusion, extracurricular activities are important settings in the lives of children and adolescents. Extracurricular participation has been associated with many positive academic, psychological, and behavioral outcomes. An examination of the nature and consequences of extracurricular participation is especially timely in an era of shrinking resources for schools. Extracurricular activities are often viewed as less important than academics and are one of the first items to be cut during fiscal constraints. Future research should examine the impact of student characteristics (e.g., gender, socioeconomic status), degree of participation (e.g., type of activity, intensity), and characteristics of activity setting (e.g., peer networks, relationships with adults) on development. This information is critical for designing extracurricular activities that are appropriate and tailored to the needs of youth from diverse backgrounds.

Failure is instructive. The person who really thinks learns quite as much from his failures as from his successes.

—John Dewey

FAILURE, EFFECTS OF

All people face obstacles and failures in a variety of life tasks. In academic, athletic, and business settings, failure feedback is often clear—receiving a poor grade, losing the game, or not getting a promotion. On a personal level, failures can range from the breakup of a relationship to not accomplishing a goal. For many psychologists, the question is not if an individual will experience failure, but how will he or she respond to it. Failure can have devastating consequences for an individual because it may confirm preexisting negative beliefs or require downward revisions in self-image or goals. Repeated failures may lead to feelings of helplessness and depression. Children experiencing failure in school may experience decreases in self-efficacy and self-esteem (maladaptive reactions). However, not all people experience these events as negative. Failure may motivate some by presenting challenges or opportunities to demonstrate competence in the future. They can use this information to change behavioral strategies to obtain success or establish attainable goals (adaptive responses).

There are many reasons why individuals respond differently to failure feedback. The general model used to assess reactions to failure consists of antecedent conditions and post-feedback reactions (including affective,

cognitive, and behavioral responses). Antecedent conditions include performance expectations, personality characteristics, and the investment in the task. After receiving failure feedback, individuals will likely experience some negative affect, make attributions about why they failed, and then behave in certain ways.

It is important to note that failure feedback is a relative term: For some individuals, a grade of C is an abysmal failure, whereas for others, it represents an outstanding accomplishment. Personal expectations and reactions from others influence one's perception of failure. When failure is unexpected or when others respond negatively to the outcome (e.g., by saying "How could you have failed?" "Everyone else did very well," or "This task was so easy"), the individual's response to the feedback will likely be stronger.

Although personality dimensions also affect how individuals respond to failure (e.g., those high in neuroticism or having a high need for achievement will likely respond differently than those who are low on these scales), most educational research has addressed the individual's orientation to the task. Carol Dweck and Ellen Leggett argue that motivational orientation can predict adaptive and maladaptive responses to failure feedback. An individual's motivational orientation influences how he or she will evaluate feedback based on his or her goals. Those who have learning (or mastery) goals focus on understanding, knowledge, and improvement. These individuals are motivated to

understand, and the feedback informs them if they have mastered the material. Individuals setting performance goals seek to demonstrate ability or to gain favorable judgments from others. These individuals are motivated to defend or enhance their self-worth, and therefore, feedback is something used to make social comparisons of themselves with others. Carol Midgely and colleagues developed the Patterns of Adaptive Learning Survey to assess performance orientation. This test assumes that motivational approaches are independent, such that individuals can be high on one, both, or neither dimension.

Understanding this motivational approach can help researchers understand how individuals approach tasks and how they respond to feedback. Learning-oriented individuals tend to believe that intelligence and many other abilities develop through effort (incremental theory). They seek out tests or other performance indicators to provide them with a sense of their current ability level. When they encounter failure, they attribute causality to lack of effort. Mistakes indicate areas where more effort is needed. When faced with similar tasks in the future, they will often modify their behaviors to spend more time on mastering the task. They do not show significant decreases in self-efficacy or self-esteem. Although they experience negative emotions following failure, they show more self-compassion, offering kindness and understanding toward self, gradually decreasing the negative emotions. These individuals may reevaluate their goals, the value of the task, or the importance to mastering the material, but then they tend to avoid maladaptive responses.

On the other hand, individuals focusing on performance goals believe that abilities (including intelligence) are fixed and uncontrollable (entity theory). These individuals can adopt different goals for testing situations. Those with performance-approach goals desire feedback to gain a favorable judgment, whereas those with performance-avoidance goals avoid situations where there could be a negative judgment. In both cases, these individuals view the potential for making a mistake as threatening. These individuals tend to attribute failure to ability ("I am not smart") or external causes ("The teacher hates me"). In either case, these individuals experience decreased self-efficacy and self-esteem. They also show lower levels of self-compassion, leaning toward self-pity (exaggerating their personal suffering). Performance-avoidance goals are associated with fear of failure; these people view testing situations as threatening, and this leads

to increases in worry, fear, and anxiety. For these individuals, even success can be interpreted as "not failing." Not surprisingly, those motivated by performance goals tend to avoid situations where there will be future challenges.

Teachers, coaches, friends, and relatives often desire to reduce the negative consequences of failure for an individual and motivate him or her to succeed in the future. Although it is difficult to change an individual's motivational orientation directly, some researchers suggest that changing attributional responses can lead to more adaptive behaviors. Jeffrey Noel, Donelson Forsyth, and Karl Kelley suggest attributional retraining as a first step in helping students cope with failure. This approach provides students with models of adaptive attributional responses to failure. Students are encouraged to focus on internal controllable attributions (effort) and to avoid internal stable (ability) or external attributions. Compassionate social support is also helpful when it focuses on mastering the material rather than on evaluating the person. This strategy has yielded some success but requires more research.

Receiving failure feedback generally is a negative experience for most people, although the longer-term effects vary greatly. These individual differences can be partially explained by individual's motivational orientation. Those with a learning (mastery) orientation respond to failure with more adaptive responses than those with a performance orientation. These orientations represent complex approaches to tasks that include implicit theories of the task and the self. In helping others effectively cope with failure and persist on tasks, social support is important, specifically when it encourages the person to focus on effort and other controllable attributions.

FAMILY INFLUENCES

Family influences are factors, characteristics, or behaviors exhibited by the family that can bring about changes to one or more members of that family. Though there are numerous and diverse family arrangements, research has often focused on the relationship between the parent and the child. Because parents are generally considered the primary caregivers in the family, they have a great influence on their child's biological, social, emotional, and intellectual development. Depending on the context, family influences can contribute to positive outcomes for the child as well as negative outcomes.

Genetic and Environmental Influences

One important family influence factor is the fundamental fact that parents pass their genes on to their biological children. Genes can determine the child's physical characteristics (e.g., eye color, hair color, and height), how the child's body will function, and even personality. In addition, there has been evidence that suggests that genetic factors, along with environmental influences, can contribute to the etiology of a variety of mental health and physical health disorders, such as schizophrenia, clinical depression, substance abuse, and different types of cancer. For example, a parent may pass on genes that convey risk for a specific disorder, such as schizophrenia, or a biological disposition or temperament that may allow the child to become more vulnerable only in risky social environments. If a parent or relative has a history of major depression, then the child is two to three times more likely to develop this condition than those who

do not have a parent or relative with depression. For parents with a history of alcohol or substance abuse, research evidence suggests that certain genetic influences (e.g., comorbid psychiatric disorders in parents) substantially affect the likelihood that children will develop alcohol abuse or other psychological disorders as they reach adulthood. The implication for these findings is that there may be a major genetic or hereditary influence interacting with the environment that can lead to specific developmental outcomes for the child.

However, well-functioning families can protect children who are at genetic risk and circumvent processes that usually lead to negative outcomes. For example, adopted children who are currently living in dangerous communities and whose biological parents have a history of criminality are more likely to display criminal behaviors than are adopted children living in safer neighborhoods. If these at-risk children are adopted into stable and loving families who live in safer and more supportive environments, the children's risk of developing criminal or antisocial behavior is decreased significantly. Therefore, genetic vulnerabilities that are expressed only in the presence of environmental triggers, such as parenting or environmental contexts, suggest that interpersonal and family influences can also play a significant role in the child's development.

Attachment

The behaviors of parents and caregivers influence children's behaviors and personalities as early as infancy. When emotional bonds are formed between the parents and the child, this process is known as *attachment.* There are two general types of attachment: secure and insecure. Parents, particularly mothers, who form a secure attachment with their children, are available and responsive to their child's needs and establish a sense of security within the child. Though infants initially exhibit distress when separated from their parents, the infants will reconnect warmly with the parents when they return. When frightened, securely attached children will constantly seek comfort from their parents or caregivers. These children know their parent or caregiver will provide security and reassurance, so they are comfortable seeking them out in times of need. As these children grow older, they become friendly, cooperative, and self-confident, and they adjust easily to the classroom

environment and establish amicable relationships with teachers and peers.

Children with insecure attachments to their parents, that is, children who do not have the opportunity to form such a relationship in early development, can become immature, dependent, and prone to disruptive and externalizing behavior disorders later on in life. Insecure attachment can be divided into three different groups: avoidant, anxious-ambivalent, and disorganized. Parents of children who exhibit avoidant attachment are often unavailable and unresponsive to the children's needs. As children grow older, they find it difficult to allow themselves to trust or depend on others and often prefer working alone. Children with anxious-ambivalent attachment to their parents tend to be anxious in their environment, even with their parents present. These children will often become resentful and resistant when the parent initiates attention. As children with anxious-ambivalent attachment reach adolescence, they may display social and emotional difficulties because their behavior in relationships may be perceived as needy or clingy by other people. Parents of children with disorganized attachment are seen as abusive, frightening, and severely neglectful of the child's needs. These children often show a mix of avoidant and resistant behaviors. For example, the children may exhibit dazed behavior and are often confused and apprehensive when the parent is present. Disorganized attachment appears to be a significant predictor of later childhood maladaptation, in which older children and adolescents are more vulnerable to a variety of emotional, social, and moral problems, such as aggressive and antisocial behavior.

Parenting Styles

Closely related to attachment, parenting and the parent–child relationship have been implicated repeatedly as correlates of child development both in normative situations and under adverse conditions. There are three different types of parenting styles: authoritative, authoritarian, and permissive. Parents who display an *authoritative* parenting style provide a loving and supportive home environment, hold high expectations and standards for performance, explain which behaviors are or are not acceptable, enforce household rules consistently, and include children in decision making. Though these parents are very responsive to their child's needs, they are demanding as well. Children with authoritative parents are often cooperative, energetic, self-confident, and cheerful. They often perform well academically, establish strong interpersonal relationships with peers, and show self-control and concern for the rights and needs of others.

In contrast with authoritative parents, *authoritarian* parents are highly demanding and directive and enforce strict rules without explanation or compromise. They provide well-structured environments and expect their children to obey them without question or flexibility. Children who are raised by authoritarian families tend to perform moderately well in school and be uninvolved in problem behavior, but they are often unhappy, anxious, and lacking in social skills. They also are more likely to exhibit higher levels of depression than are children from authoritative families. On the other hand, *permissive* parents are highly responsive to the children's needs but are not very demanding, as there tends to be very little structure within the home environment. Permissive parents do not require mature behavior from their children, provide no consistent set of rules, and often avoid confrontation. Children from permissive families are more likely to be involved in problem behavior and perform less well academically, but they often exhibit higher self-esteem, better social skills, and lower levels of depression than children from authoritarian or authoritative families.

Family Influences as Risk and Protective Factors

Research on risk and resilience shows that families can function as direct or indirect influences on child behavior. Family characteristics or behaviors that predict psychopathology or negative child outcomes are described as risk factors. There has been research aimed at identifying representative risk factors in development of cognitive and social-emotional competence within the family context. Some of these variables include a history of maternal mental illness, high maternal anxiety, negative or few parental interactions with the child during infancy, minimal parental education, disadvantaged minority status, stressful life events, large family size, poor family relations, and parental criminal behaviors. Many times, it is not only a single risk factor in the child, family, or environment that leads to negative outcomes but a combination of these factors that contribute to the problem in the family.

Effects of the family that demonstrate positive or desired outcomes for the child are described as protective factors for the child. Although resiliency

research has focused primarily on personal attributes, recent research also examines protective factors in a social and family context. There are currently three broad sets of variables that have been found to operate as protective factors for positive child development: (1) characteristics of the individual child (e.g., temperament, cognitive ability); (2) families that provide warmth, support, and structure; and (3) the availability of external support systems. These protective factors can help children from very high risk families and environments to avoid negative outcomes (e.g., academic failure, delinquency, depression, and substance use) and also develop successful and positive life adaptation.

Family Influences as Moderator Variables

Family influences can act as *moderator variables*, such that the influence of the family can alter the effect of another condition or factor on the child, in either a positive or negative way. In situations where there are moderating factors, there is a conditional or joint effect present, which determines the direction and/or the strength of the relationship between the predictor variable and the outcome. In one common type of interaction, positive family influence functions as a buffer to shield the child from any harmful exposure to, or impact of, adversity. For example, a protective family provides shelter and security for the child in an unsafe community so the child will not be harmed. Protective factors can often be activated by adverse events, in which parents are compelled to protect their child if they perceive that their child may be at risk or in danger. In other situations, family influences may exacerbate the effects of already-negative contexts or risk factors. For example, lack of monitoring by the parents (i.e., moderator variable) may be unsafe for children residing in bad neighborhoods (i.e., negative context) because these children do not have the security they need to live safely in these neighborhoods. Therefore, the quality of monitoring by parents in risky or dangerous environments can be described as a moderator.

Individual differences in children and parents can moderate the effects of the family as a whole, suggesting a reciprocal relationship involved. Parents can change their own perceptions and behavior in relation to their children's developmental changes and also according to how their children respond. Differences in child temperament and personality can be

moderator variables of parent behavior, and these ways of relating to people and the world often change over the course of development. In addition, the quality of parenting can be moderated by ecological systems that regulate parent behavior, such as parents' marital status, the extended family, and the social systems of work, culture, or community. For example, a supportive spouse or grandparent can be a protective factor for the children during periods of stress and hardships experienced by the family, by regulating the behavior and affect of the parent. If parents experience numerous problems at work, these problems might influence their parenting style when they come home, thereby affecting the behavior of the child.

Family Influences as Mediator Variables

Whereas a moderator variable influences the strength of the interactions between variables and the outcome, *mediator variables* serve to explain the relationship between the predictor variable and outcome. Diverse family influences can serve as mediator variables that explain the child's outcome. For example, parental involvement in a child's education is a protective factor that contributes to positive child academic performance, such as high attendance and graduation rates, improved homework completion, and decreased violence and substance abuse. Parents often intervene in their child's education if they discover that their child is failing in a subject area. As the parents work with teachers and with the child in the school, the child's grades eventually improve. Thus, parental involvement in the school acts as a mediating variable, because it helps explain how the child was able to achieve positive academic results. Parental influences can potentially mediate many risk factors, including genetic disorders, low social class, or economic difficulties, in addition to academic failure. For example, in studies that explored the genetic and environmental effects in the development of resilience among children in poverty, researchers found that maternal warmth and support mediate the effects of genetic risks to adaptation in unfavorable circumstances.

However, family influences as mediator variables can also help explain undesirable or negative child outcomes. If a child's parents are physically abusive or neglectful to the child's basic needs, this might help explain why the child is experiencing academic and social-emotional difficulties. Therefore, parenting styles

and attachments may also act as mediator variables that can affect the child's psychological well-being. Families can produce all kinds of risks, resources, and opportunities for the same child over the course of development, varying from biological and societal factors to academic and economic resources.

Family influences can also have an indirect effect on the child when the influence is mediated by intervening factors and the processes the factors represent. For example, mediator variables can be features of the child, the child's nutrition, the school, the neighborhood, the community, or any other system outside of the family that influences the child's behavior. One example of this type of mediating factor is school support, which can influence both the family and the child, especially if the family has very little education and few economic resources available to assist in their child's education. School support, therefore, acts as a positive mediating variable to improve the child's academic skills even when the family is unable to help the child succeed in school (e.g., because of stressful conditions or difficult circumstances the parents are facing).

Families Influences as Sources of Risk

Because parents are an integral part of the child's lives, they can also be a potential source of threat to their child's development and well-being. These influences can be passive in nature. Although some actions may not be necessarily deliberate, family members may harm their children's well-being through neglect or incompetence. Parents who have a physical or cognitive impairment or other mental health disorders may not be able to provide normative levels of nutrition, security, or teaching for their children, or they may not be able to notice impending danger and take protective action, which can place the child at risk for negative outcomes. Socioeconomic status and functional competence of the parents are often associated with child competence and academic achievement. For example, incompetent parents may be more likely to expose their children to danger, deviant peers, or other harmful influences in the environment due to their circumstances, choices, or behaviors. Younger children, who are still exploring their environment, are especially vulnerable to these hazards and risks if parents do not pay attention to or monitor their safety.

Family influence can also be an active source of threat. One example of this type of threat is child abuse and maltreatment, in which parents inflict physical and/or psychological harm on the child, affecting the child's welfare and safety. Studies have shown that child maltreatment perpetrated by a parent is a direct threat to children, and studies suggest that maltreatment by an attachment figure inflicts more harmful physical and/or psychological effects on the child than does maltreatment by a stranger. Children who experience maltreatment are at risk of developing health and psychological problems as adults, such as substance abuse, eating disorders, and depression. Children whose parents use harsh disciplinary methods can become defiant, explosive, and unpredictable. Even those from exceptionally abusive families tend to experience emotional difficulties and low self-esteem. In addition, because children are also social learners, children observing domestic violence or parental conflict may be disturbing for younger children, affecting their sense of security within the home environment.

There has been extensive research that explores family contextual factors for early-onset substance use (e.g., alcohol, marijuana) as children reach adolescence. Besides child abuse and maltreatment stated earlier, children whose families experience extreme poverty are considered to be at higher risk for a very early onset (before age 13) of alcohol or substance use than other children. In addition to low socioeconomic status, other early family contexts that have been shown to enhance risk for early-onset substance use include being raised in a family without a biological parent, parental stress, family medical conditions, and unemployment. However, one of the most potent risk factors is living with a parent who abuses alcohol and other substances. Research suggests that parental alcoholism and substance use significantly increase a child's likelihood that the child will experience substance use in adolescence.

Divorce, Remarriage, and the Family

Parental divorce and remarriage have an influence on the child's well-being, behavior adaptation, and academic performance. Children and adolescents whose parents are divorced or in the process of getting a divorce are at a high risk of developing externalizing behavior problems, such as antisocial behavior, aggression, and noncompliance. In addition, children and adolescents may develop internalizing behavior problems, such as depression, anxiety, low self-esteem,

and withdrawn behavior. However, parental divorce may be considered a positive solution for some families, if there is an extremely high family conflict involved. Family conflicts that involve hostility and abuse lead children to develop negative emotions that can be destructive; thus, a divorce may be an appropriate solution for the family to prevent the child from witnessing or experiencing this conflict. There may be some children who feel they are caught in the middle of this conflict or even feel helpless during this stressful period. Research suggests that parental marital hostility is associated with lack of emotional regulation in children and adolescents, which can lead to behavior problems in the future.

Marital transitions can bring positive and negative life changes to the family. Although divorce leads to an increase in stressful life events, such as poverty and psychological problems in adjustment for both child and parent, it also may allow parents the opportunity for personal growth. Remarriage provides the family an additional adult as a resource for family management and child support; however, parental monitoring tends to be lower in stepfamilies and in single-parent households than in nuclear families. In the early stages of a remarriage, stepparents are often less affectionate with their stepchildren even though they spend time with them attempting to form a relationship. In addition, biological mothers often become inattentive and less affectionate and more irritable and inconsistent in discipline. It may also be difficult for children to adjust having a new parent present especially if they still desire their biological parents back together.

Children with certain individual and family protective factors may be less likely to exhibit negative emotional and behavior outcomes after a divorce or remarriage. They may possess coping strategies, strong relationships with parents, or social support, which help children to experience less stress and emotional instability. Authoritative parenting throughout the divorce or remarriage can improve child outcomes as well. Parents who are able to provide warmth and support, along with control and monitoring of their child's behavior, can lead to diminished externalizing behavior and increase social responsibility in children and adolescents. Nevertheless, there are many challenges that arise in stepfamilies as parents try to build a marital relationship in the presence of their child and the child tries to develop meaningful and secure relationships with biological parents, stepparents, and stepsiblings as well.

Family Influences in Social and Cultural Development

Parents have numerous roles and responsibilities to teach, model, and socialize with their children in order for them to learn and adapt in their social environment. Beginning early in life, most children learn that there are some things they can or should do and other things they should not do. For instance, children learn lessons about their culture's standards and expectations, such as personal hygiene, table manners, and interpersonal skills such as knowing when to say "please" or "thank you." However, they also learn from parents not to interrupt when an adult is speaking, not to turn in homework late for school, and not to hit other children. Parents therefore attempt to instill beliefs that are acceptable in their own society. They shape or model their child's behavior through rewards and punishment, and reciprocally, the child can also influence and shape the parent's behaviors through interactions with the parents.

Families also have cultural values and beliefs systems that may influence their child to adopt those same values and beliefs or even different ones. Parents from culturally and ethnically diverse backgrounds teach or expose children to various rituals and traditions that are part of their family life. Children learn to pray or meditate and to participate in culture-specific or religious rituals. Families also have their own histories and life stories that serve many functions for children, such as imparting family values or life lessons. In various ways, parents play an important part in establishing their child's social and cultural identity through both direct education and indirect provision during their child's growth and development.

In some families, for example in Latino, Native American, and Asian communities, family bonds and relationships are especially important, and extended family members often live nearby. Children who are raised in these cultures are likely to feel responsible for their family's well-being and display loyalty and respect for their elders. It is not unusual for a child to leave school when help is needed at home. School achievement is also highly valued, and most parents encourage their child to do well academically. However, there are a few cases where academic achievement may be less valued than achievement in other areas. For example, in some Polynesian families, parents expect children to excel in creative arts and dance rather than academic subjects such as reading and writing. Therefore,

families have cultural expectations that may influence what their child is learning in school.

Many families also have different attitudes, beliefs, and perceptions about their role in their child's education, which can affect how parents communicate with teachers in their school. The customs and beliefs of culturally diverse families often conflict with those of the educational system. For some immigrant families, parents have beliefs and expectations that teachers are the experts in educating children; therefore, parents may not want to interfere in their child's schooling. For other families that are close-knit, they prefer to resolve their child's academic difficulties within the family rather than with school professionals. In addition, linguistic barriers make it difficult for parents to communicate with teachers, especially if their child is having academic or social problems in the school. Addressing these concerns may potentially help schools and parents build the partnership necessary to improve the child's learning in the school.

Family influences contribute to a child's development in positive or negative ways. They may be sources of risk and adversity or sources of support and protection. The accumulation of many risk factors leads to many problems in children; however, having the child exposed to a variety of family protective factors can contribute to positive outcomes. Parents provide resources in the family, teach children values and family traditions, and allow children opportunities to develop their skills academically and socially. Thus, in direct or indirect ways, families influence their child's development across multiple domains including the child's competence, physical and psychological well-being, adjustment, and life successes.

FIELD EXPERIMENTS

Field experiments are randomized interventions that take place in naturalistic settings, as opposed to research laboratories. Education experiments may take many forms. Examples include preschool readiness programs, curriculum supplements, reductions in classroom size, and alterations in the cooperative format of the classroom, as well as larger institutional interventions, such as voucher systems that allow parents to choose among schools. In each case, field experimentation involves the random assignment of students, classrooms, or schools to treatment and control conditions.

The primary purpose of experimentation is to isolate causal relationships. Random assignment ensures that exposure to the intervention bears no systematic relationship to background factors, such as students' home environment or peer influences. Field settings enable the researcher to draw causal inferences under naturalistic conditions, which enhances the external validity of the results. Field experiments strive to address four aspects of external validity: (1) How closely does the intervention resemble what will be deployed in other settings, for instance, as the result of a new policy initiative? (2) To what extent was the experimental stimulus delivered in a context that resembles the setting within which the intervention is likely to be deployed in the future? (3) How closely do the subjects in the experiment resemble those who are likely to be presented with the intervention? (4) How closely do the outcome measures resemble

the outcomes of most interest from a policy or theoretical perspective? The ideal field experiment is one that is conducted as unobtrusively as possible, using subjects and interventions that allow for generalization and outcome measures that meaningfully gauge the short- and long-term effects of the intervention.

Field experimentation is especially useful in educational environments where the intervention and setting interact in complex ways. Here, the advantages over laboratory experimentation or observational research are clear. For example, to test the influence of class size on student performance, researchers in a laboratory study might divide subjects into different sized groups for an afternoon to see how quickly the subjects learn a new skill, such as long division. A researcher conducting an observational (nonrandomized) study of the effects of class size has the ability to observe actual classroom behavior but is unable to distinguish the apparent effects of class size from other factors, such as school funding and parental involvement; even the use of multivariate statistical methods leaves open the possibility that the treatment and control groups differ systematically in unmeasured ways. A field experiment that randomly assigns students to different sized classes during elementary school has the potential benefit of isolating this one change in the students' educational environment while maintaining the advantages of unobtrusive measurement within a naturalistic setting.

In practice, field experiments often confront practical challenges. Schools and parents may be unwilling to participate in a randomized study or to adhere to a protocol that, for example, assigns some students to classes with lower student–teacher ratios. In a class size experiment, for example, parents may withdraw their children from large classes and exit the school or pressure administrators to reassign them to small classes. This problem of noncompliance may be correctable using statistical methods such as instrumental variables regression, where the instrument is assignment to the treatment group and the independent variable is whether or not the subject received the actual treatment. Noncompliance, however, not only complicates the analysis and interpretation of the results; it also undermines the statistical power of the experiment. More difficult to correct statistically are problems of attrition, as occur when subjects assigned to one experimental group are more likely than those in the other group to exit the study. A third problem is spillover, or indirect treatment of some subjects as

a function of other subjects receiving a treatment directly. For example, if improving the educational environment among children in small classes has positive educational effects on their counterparts in larger classes, a simple comparison of treatment and control groups will underestimate the effects of the intervention. Finally, field experiments are potentially susceptible to Hawthorne effects. The mere fact that an intervention is administered under the watchful eye of the evaluator may change the quality of the intervention or the manner in which participants respond to it.

The use of randomized field experiments also raises ethical considerations. Exposing students to varying interventions may be interpreted to mean that some students will be denied, for the sake of science, the best education possible. Given this ethical concern, researchers may be unable to deny access to existing services by removing pieces of an established program; instead, they must augment an existing program with new benefits and compare the effects of these changes to the baseline outcomes of the preexisting program. Sometimes resource limitations create opportunities for acceptable randomized interventions. For example, if school vouchers are in limited supply, and receiving a school voucher is determined by a lottery, researchers may discern the influence of the voucher program by comparing the educational outcomes of those who were randomly selected to receive a voucher to those who applied but were not selected.

When field experiments are impractical for logistical or ethical reasons, researchers may examine natural experiments, that is, situations in which events or institutional practices sort subjects into treatment and control groups in ways that mimic randomized assignment. For example, when a benefactor offers college scholarships to all third graders in a given school, one may examine the effects of this incentive program on graduation rates by comparing to these third graders the corresponding outcomes of second and fourth graders in the same school. Similarly, it is possible to examine the influence of kindergarten enrollment on a child's intellectual development by comparing children whose birthdays fall immediately before and after a specific cutoff date. Natural experiments permit researchers to examine the consequences of "as if" random variation. The drawback of natural experiments is that "as if" randomization is not necessarily the same as actual randomization. The researcher may be mistaken in asserting that the treatments were applied

in a random fashion, in which case, causal inferences may be biased.

FIELD INDEPENDENCE– FIELD DEPENDENCE

Field independence–field dependence (FI/D) is a dimension of cognitive style that affects the degree to which individuals rely on their own internal frames of reference in perception and performance of cognitive and social tasks. The degree of reliance on internal or external referents, in turn, affects other cognitive and social domains of behavior. The result is the portrait of a field independent person who is perceptually and cognitively analytic—able to see the trees in the forest. The same person is socially introverted, thinking his or her own thoughts rather than engaging with others. The field dependent individual perceives and thinks more holistically and can even be overwhelmed by extensive data in the field—unable to engage selective attention without help. The field dependent person relies on others for direction, help, and confirmation and thus exhibits a socially engaged interpersonal style. People develop from a relatively field dependent style as children to more field independent with age, but this general developmental trend does not have a uniform outcome, and therefore, FI/D remains a variable of individual difference within the adult population.

The descriptions of individuals falling at the extreme ends of the FI/D continuum are immediately recognizable by any teacher. Some students seem to take off on their own, cognitively speaking. These field independent learners like to work independently and even get impatient when they are placed in a group for discussion and problem solving. Their field dependent counterparts are happy when it is time for group work. They are lost on their own and, therefore, subscribe to the notion that two heads are better than one. The fact that these types of individuals are so recognizable to teachers may be one reason that the construct of FI/D remains important in educational psychology.

A second reason is that all educationalists are attracted to the idea that individual differences in students can be characterized in terms of *style* rather than solely in terms of *ability*. A style is expressed on a horizontal continuum with neither end being inherently superior to the other. Ability is expressed using a vertical metaphor, with some students on top and others at the bottom. The top is good; the bottom is not. Bottom students need remediation; top students do not. Differences in the style continuum suggest that all learners can do well if they are situated in the appropriate learning environment. In this sense, cognitive styles such as FI/D are the predecessors to the idea of multiple intelligences, which also has appealed to teachers. The utility of these conceptions of individual differences is in the promise they offer for learners and the responsibility they place on educators for structuring instruction in a way that helps learners to succeed.

Despite the conceptual attraction that the FI/D construct holds, the empirical research on this construct has been plagued by measurement problems. The original measure of FI/D in the mid-1900s was administered

individually and required the examinee to orient perceptually and physically to a field of objects as they were rotated. This cumbersome procedure was replaced by the Group Embedded Figures Test, which consists of a booklet containing line drawings in which examinees are to find hidden shapes. The rationale for the task design is that children with the field independent style will succeed in finding the hidden shapes without becoming distracted by the overall figures. The task resembles sections of intelligence tests that measure fluid ability, which is one aspect of some definitions of intelligence. Indeed, the Group Embedded Figures Test has been found to load on fluid ability when factor analyzed. Moreover, the scoring of this measure results in an overall score indicating number of correct responses; a high score means high field independence. In other words, this measure transforms the attractive, value-neutral style construct into a value-laden ability. Some connection undoubtedly exists between the field independent end of the style continuum and the field independent ability (or fluid intelligence) measured by the Group Embedded Figures Test, but research attempting to understand the role of the FI/D style in learning requires better measurement procedures.

Because of the measurement problem, some researchers have become discouraged about the utility of FI/D as a construct that can help educators understand learning. However, others see this construct as extremely salient for success in the variety of contexts that learners face today and, therefore, these researchers attempt to improve its measurement. Moreover, research results typically reveal a weak to moderate correlation between the Group Embedded Figures Test and measures of learning success under particular conditions, such as classroom second language learning. In other words, empirical results, although not dramatic, are sufficient to keep some researchers interested. In particular, researchers studying learning through technology see FI/D as an important means for understanding how individual differences intersect with technology use.

Can instruction be designed in a way that fits individual styles? Can online instruction be modified on the basis of dynamic assessment of style? Can teachers use technology to provide individual and social alternative learning environments for learners in the same class? These are some of the questions that researchers hope to address, but in order to obtain results about the success of such learning conditions,

a valid measure for assessing the FI/D style is needed. Whereas findings about individual differences may have been difficult to act on in classrooms, the range of learning options availed through technology prompts researchers to seek solutions to measurements issues.

FLASHBULB MEMORIES, THE NATURE OF

Psychologists interested in people's memories of life events have suggested that memories of some events may be different from others in that people are able to recall not only the events but also the *circumstances* surrounding the events and, further, that these memories may be more detailed and subject to less forgetting than others. These memories have been termed *flashbulb memories.* Two fundamental questions psychologists have posed with regard to flashbulb memories are whether they are somehow special with regard to the nature of the information stored about the event and whether they respond differently to the ravages of time than other memories. Another important question is what factor or factors contribute to the formation of a flashbulb memory. In other words, what, exactly, is necessary for individuals to form a flashbulb memory?

Flashbulb Memories and the Study of Memory in General

Psychologists interested in how individuals acquire and use knowledge have devoted much attention to the study of memory. Indeed, there have been more studies of memory than of any of the other cognitive processes that psychologists have investigated. From both a theoretical and practical standpoint, the study of memory is important and provides valuable information to psychologists and educators about the way to best present material to enhance learning, the most effective strategies to promote remembering, and an understanding of the variety of factors that often serve to limit how much individuals can remember. Much attention has been paid to how individuals of all ages encode, store, and retrieve information they have experienced. The study of memory has had a long history in psychology and remains a topic of great study and fascination today.

Psychologists have found it helpful to categorize memories into short-term and long-term memories. Short-term memories of newly presented information, such as someone's phone number, may last for several seconds but are often displaced when individuals are distracted in some way or kept from rehearsing the information. Thus, a new phone number that one has looked up and intends to dial may be lost as one answers a question posed by a child entering the room. Chances are, if the information is not familiar, for example, if this is the first time that one has attempted to think about or remember this particular phone number, the phone number that is displaced is unlikely to be remembered at a later time. It has, for all practical purposes, vanished. Long-term memories are generally thought to be more permanent than short-term memories (although all long-term memories are not necessarily permanent) and can last for several minutes up to several years. An adult's recall of the first day of kindergarten, assuming that such a memory exists, would be a good example of a long-term memory. People's ability to recall information can be very impressive, as in the case of many long-term memories, or not, as in the case of many short-term memories.

Long-term memories are generally classified into one of several types of memory. Within the broader category of long-term memory are *episodic* memories, or memories for events; *semantic* memories, or memories for general knowledge (e.g., that a kangaroo is a type of mammal); and *procedural* memories, or memories for procedures involved in various skills (e.g., in typing or playing the piano). A flashbulb memory is a type of episodic memory.

With regard to episodic memories, psychologists have been particularly interested in the numerous factors that produce either heightened or hindered recall of an event. As mentioned earlier, individuals' long-term memories can be quite impressive. What are the characteristics of an event that may make one's memory for the event particularly salient and long-lasting? Are some memories so "special" that they may be even more salient and long-lasting than others? These are questions that have intrigued not only psychologists but also individuals in all walks of life.

Studies of Flashbulb Memories

An early article by R. Brown and J. Kulik is generally thought to be the first article detailing an examination of flashbulb memories. The article is quite important, because it motivated others to begin to examine flashbulb memories in a systematic manner and because the authors presented somewhat inconsistent conceptualizations of flashbulb memories. Brown and Kulik suggested that when individuals experience an event in their life that is highly unexpected as well as consequential, they are likely to remember not only the event but also the contextual circumstances surrounding the event. So, for example, an individual might still remember the circumstances surrounding being told that her father died (such as the time of day, the activity being engaged in, where she was when given the news, what happened immediately afterward), even though several decades have passed, or upon hearing the news of the *Challenger* explosion. It should be noted that psychologists have most often studied individuals' memory of public rather than private events. Because of their nature, highly unexpected and consequential public events are likely to produce memories in a large number of people, making public memories more open to psychologists' investigations than are more personal and private flashbulb memories. Thus, psychologists know more about public than private flashbulb memories.

In an initial study conducted by Brown and Kulik, individuals were asked, in part, whether they recalled the personal circumstances of hearing the news that President John F. Kennedy had been assassinated (since Brown and Kulik's study, psychologists have investigated several other highly surprising and

consequential events, such as other assassinations, the *Challenger* explosion, the Loma Prieta earthquake, and the terrorist attacks in the United States on September 11, 2001). To have what Brown and Kulik considered a flashbulb memory, participants had to indicate that they did, indeed, remember the circumstances surrounding being made aware that Kennedy had been killed and also had to be able to provide information about at least one of six "canonical" categories of contextual circumstances (place, ongoing event, informant, affect in others, own affect, and aftermath). What is interesting about Brown and Kulik's operational definition of flashbulb memories is that it would clearly seem to "pave the way" for the allowance of forgetting in flashbulb memories. However, at the same time, Brown and Kulik suggested that individuals might remember the circumstances surrounding a surprising and consequential event because of the potential biological significance of the event and the relatedness of the event to survival of the species. Thus, the authors emphasized the importance of remembering the event to a species' very survival and, further, suggested a photographic metaphor to describe the mechanism by which these types of memories might be formed. Even the term used by these authors, *flashbulb memories*, suggests that such memories have rich details that are frozen in time, much like a photograph. Thus, depending on which of Brown and Kulik's conceptualizations one focuses on, he or she may end up with the understanding that flashbulb memories are special and involve little forgetting or the understanding that flashbulb memories may be special, but, perhaps, not so special.

Since Brown and Kulik's study, several investigators have examined individuals' reactions to surprising and consequential events to determine the nature of flashbulb memories. One important debate in the literature has been whether flashbulb memories are different enough from other memories to suggest that they must be formed differently than are other memories. If so, flashbulb memories for important events in people's lives (and the circumstances of hearing about the events) may be impervious to the types of rampant forgetting that individuals experience for more mundane events. To examine the "special mechanism" hypothesis, psychologists have frequently examined individuals' ability to recall the circumstances of hearing about a surprising and consequential public event fairly soon after hearing of the event and then again, after a longer delay. For example, individuals

might be asked a series of questions regarding their memory of hearing about the *Challenger* explosion a day after the news event and then again 6 months or 1 year later. Of interest is whether individuals remember the event and the circumstances of hearing about the news event and whether their memories of the event and circumstances after a delay are similar to those they had initially. It is generally assumed in this type of research that individuals' initial recollections, typically examined within days of the event, are accurate.

When psychologists have examined individuals' memories of public events in this way, it has generally been the case that individuals' memories are not consistent over time and involve a loss or distortion of details. Some recent research suggests that these types of changes are less likely to occur when the initial memories are investigated about a week or so after the event, rather than immediately following the event. In any case, it appears that flashbulb memories are not so special as to warrant the hypothesis that they are formed from a special set of processes. Some psychologists have found, however, that individuals often have a great deal of confidence in their inaccurate memories. Thus, although the individuals' memories for important events may not be accurate, these individuals believe that their memories are accurate.

Another important issue is what factor or factors are necessary to form a flashbulb memory. Psychologists have examined the role of several variables in the formation of flashbulb memories, including rehearsal, emotional state, importance or consequentiality, surprise, novelty, and prior knowledge. Psychologists have also developed and tested fairly complex models of how these variables might interact to produce flashbulb memories. It does seem clear at this point that some of these variables may play a more crucial role in the formation of flashbulb memories than others. Psychologists are continuing to refine their models of flashbulb memory formation.

Although it is now generally agreed upon that flashbulb memories involve forgetting, it is also the case that individuals' memories for some events, and the circumstances of hearing about the events, can be impressive. There have been cases in the literature, for example, of older adults recalling a striking amount of details for crucial historical events that occurred decades earlier. For this reason, psychologists have begun to concentrate on identifying the circumstances leading to such superior memory. It

appears that rehearsal may be critical in the formation of flashbulb memories, as individuals retell important narratives about their life history. It also appears that direct involvement in an event may be an important component in the formation of flashbulb memories. For example, living through an event such as an earthquake or being in close proximity to such an event leaves a much stronger impression than hearing about this event from many miles away. Thus, there is a difference in having "been there" for something like the Loma Prieta earthquake or the 9/11 attacks in New York City. As research on flashbulb memories continues to progress, psychologists will no doubt discover other important factors related to the formation of flashbulb memories and gain an even greater understanding of what factors are responsible for the very impressive memory for circumstances that may occur in some situations.

FLUID INTELLIGENCE

Fluid intelligence is the set of cognitive processes that people bring to solving novel tasks and representing, manipulating, and learning new information. Consequently, fluid intelligence is an important construct in educational psychology because it attempts to describe and explain aspects of the individual that influence how, and how well, people solve unfamiliar problems and learn previously unfamiliar material. The history, nature, and current controversies surrounding fluid intelligence are herein reviewed.

History

Early research in intelligence proposed that intelligence was composed of a single, unitary characteristic (known as general intelligence, or g) and a relatively large number of specific abilities. Whereas g was viewed as broad ability having a profound effect on learning, problem solving, and adaptation, specific abilities were viewed as narrow and largely trivial. However, subsequent research differentiated intellectual abilities that were based, in large part, on culturally specific, acquired knowledge (known as crystallized abilities, or g_c) and intellectual abilities that were less dependent on prior knowledge and cultural experiences (known as fluid abilities, or g_f). Although this work was primarily influenced by factor analysis of relationships among cognitive tests, prediction of future learning, experimental studies, and other forms of evidence also supported the crystallized versus fluid distinction. More modern research has identified other abilities in addition to crystallized and fluid abilities (e.g., working memory, quantitative reasoning, visualization), although scholars have not yet agreed on the exact number and nature of these abilities and whether these abilities are independent faculties or subordinate to g. In contrast, there is strong consensus on the distinction between fluid and crystallized intellectual abilities and their substantial roles in human learning and adaptation.

Nature

Contemporary neuroscience defines fluid intelligence as cognitive processing independent of specific content. Fluid intelligence is characterized by the ability to

suppress irrelevant information, sustain cognitive representations, and manage executive processes. Measures of fluid intelligence are strong predictors of cognitively demanding tasks, including learning, education, vocational performance, and social success, particularly when such performance demands new learning or insight rather than reliance on previous knowledge.

Research also suggests strong biological influences on the development of, and individual differences in, fluid intelligence. For example, studies demonstrate that (a) fluid intelligence is more heritable than most other cognitive characteristics; (b) localization of fluid intelligence operations in the prefrontal cortex, anterior cingulate cortex, amygdala, and hippocampus; (c) life-span changes associating neurotransmitter decreases with decrements in fluid intelligence; (d) moderate associations between neural speed of response/conduction and (untimed) measures of fluid intelligence; (e) that unusual exposure to language (e.g., deafness, nonstandard language background) has little effect on the development and performance of fluid intellectual abilities; and (f) fluid abilities have been rising steadily in Western countries for over a century in contrast to relatively stable crystallized abilities (i.e., the Flynn effect). Although there is an association between environmental advantages (e.g., parental education, socioeconomic status) and fluid intelligence, this association may be partly or entirely explained by gene-environment correlations. There is little evidence to suggest that deliberate environmental interventions (e.g., compensatory education programs) substantially influence fluid intelligence, although such programs may have at least short-term effects on crystallized intelligence.

Nearly all major clinical tests of intelligence include measures of fluid and crystallized intelligence. Most notably, tests that historically invoked different models of intellectual processes have recently adopted a hierarchical model in which measures of fluid and crystallized intelligence (and sometimes other abilities) are viewed as subordinate to general intelligence and are combined to produce a composite estimate of g.

Current Controversies

There are a number of unresolved issues regarding fluid intelligence. One such issue is how fluid intelligence relates to other forms of intelligence. Some have argued that general intelligence is a statistical artifact (i.e., there is no genuine all-purpose intellectual ability captured by g) and that fluid intelligence is an independent, distinct intellectual ability (i.e., the multiple intelligences perspective). Although the notion of multiple intelligences is popular among educators, most cognitive scientists hold that abilities are hierarchically arranged, with g as a superordinate construct. Some hold that fluid intelligence is synonymous with g and that g_f is, therefore, the superordinate construct in any hierarchy of intellectual abilities, but most hold that g is distinct from, and superordinate to, g_f.

Another controversy is whether measures of fluid intelligence provide a more "culturally fair" approach to estimating the intelligence of individuals from linguistically, ethnically, or culturally diverse backgrounds. Cross-cultural and cross-linguistic research generally supports this contention, as fluid intelligence tests can typically be used with few changes and still yield reliable and valid results. However, the case for ethnic groups sharing a common language (e.g., English-speaking Black and White Americans) is more controversial. Whereas measures of crystallized intelligence produce substantial differences between groups and are often cited as examples of cultural bias in assessment, the finding that measures of fluid intelligence reflect similar (and in many cases, larger) differences between groups is not as widely recognized. Although at this time, the bulk of evidence is consistent with the conclusion that tests reflect, rather than create, intellectual differences within and between groups, some scientists continue to search for explanations of differences between groups that attribute the differences to nonintellectual factors.

The processes that constitute fluid intelligence are also a matter of debate. For example, some argue that working memory and fluid intelligence are synonymous, whereas others argue that fluid intelligence is a unique characteristic related to, yet distinct from, other cognitive processes. Yet another controversy relates to the methods used to decide competing theories. For many decades, the dominant source of evidence was factor analytic. However, more recent research has invoked brain imaging, functional magnetic resonance, genetic, and other forms of evidence. The generation and integration of evidence from these disparate sources promise to help resolve current controversies, and pose new controversies, regarding the nature and definition of fluid intelligence.

FREQUENCY DISTRIBUTION

It is not only important to understand what descriptive data represent but, if possible, to see it as well. One way to do this is through the use of a *frequency distribution*, a visual representation of a distribution of data.

Table 1 shows 25 scores on a math test for which a frequency distribution will be created.

Table 1   Sample Math Scores

70	77	80	84	90
72	78	80	84	91
72	78	82	85	91
74	79	83	87	93
76	80	84	87	94

The first step in creating a frequency distribution is to define the class interval that will be used. A *class interval* is a range of numbers, and the first step in the creation of a frequency distribution is to define how large each interval will be.

Some guidelines for creating a class interval are as follows:

1. Select a class interval that has a range of 2, 5, 10, 15, or 20 data points.

2. Select a class interval so that 5 to 20 such intervals cover the entire range of data. A convenient way to do this is to compute the range, then divide by a number that represents the number of intervals you want to use (between 10 and 20).

3. Begin listing the class interval with a multiple of that interval.

4. Finally, the largest interval goes at the top of the frequency distribution.

Once class intervals are created, it is time to complete the frequency part of the frequency distribution. This is done simply by counting the number of times a score occurs in the raw data and entering that number in each of the class intervals represented by the count.

In the frequency distribution created earlier, the number of scores that occur between 80 and 84 and are in the 80–84 class interval is 8. So, an 8 goes in the column marked Frequency.

Table 2 shows the frequency distribution following the guidelines listed previously where all 25 scores are represented and can, of course, only appear in one interval.

Table 2   Sample Math Scores–Frequency Distribution

Class Interval	Frequency
90–94	5
85–89	3
80–84	8
75–79	5
70–74	4

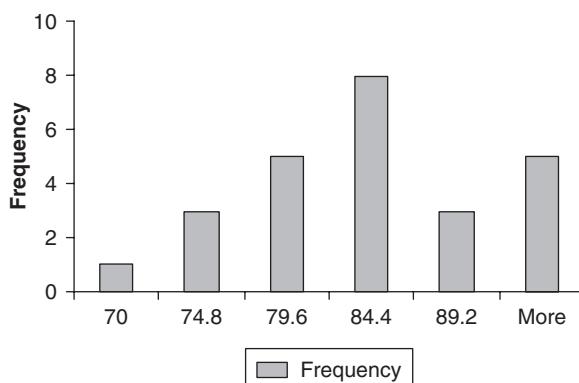
Another way to visualize a distribution of scores is through the creation of a histogram such as that depicted in Figure 1.


Figure 1   Sample Math Scores—Histogram

FRIENDSHIP

Making friends, keeping friends, and being a friend are considered important developmental tasks from early childhood to the adolescent years. Friendships set the stage for children's development of numerous competences, including communication and cognitive skills, as well as emotion regulation and emotion understanding. Friendships also allow children to measure themselves against others, to develop a sense of self-concept, and to acquire the social skills they will use throughout their adult lives. This entry discusses the role that friendships play in school adaptation, in being accepted, and in childhood development. This entry then addresses deleterious effects and other implications of friendships.

Friendships and School Adaptation

Friendships appear to play a crucial role in children's adjustment and adaptation to school. One way

that friendships may contribute to children's school performance is by directly stimulating cognitive growth and learning, thus setting the stage for later intellectual performance. Consistent with this proposal, empirical evidence suggests that children demonstrate greater problem-solving ability, task mastery, and creativity when interacting with friends than when working alone and that these skills transfer to other situations. When children collaborate with friends, they are more efficient and productive problem-solvers across a variety of tasks, including creative and oral tasks, as well as more academic tasks, such as scientific reasoning problems or writing assignments. Further evidence links the quality of children's friendships to children's academic performance. Such associations appear as early as the preschool years, with the quality of preschool children's friendships predicting academic performance in elementary school.

A second way that children's friendships may influence adjustment to school is by shaping children's attitudes and motivation toward schooling. For example, research by Carollee Howes indicates that children who moved from one day care setting to another, accompanied by friends, demonstrated higher levels of social competence than children making a similar transition without a friend. Brian Vaughn and his colleagues report a similar finding for preschool children advancing from one Head Start classroom to another. Gary Ladd and his colleagues document the positive value of entering kindergarten in the company of friends on children's adjustment. Particularly noteworthy is their finding that children who moved into kindergarten with mutual friends were better adjusted to school than children who made the transition with acquaintances who were not friends. The transition process from elementary to middle school also appears to proceed more smoothly for children who have friends. Specifically, Kathryn Wentzel found that students who had a friend upon entering middle school displayed better academic and social adjustment at the end of their first year of middle school than students without a friend. In addition to helping children cope with the normative stress that accompanies the transition to a new school, evidence suggests that friendships may help children cope with nonnormative stresses such as becoming the victim of a school bully. In contrast, children without friends not only report being lonely and feeling depressed but also exhibit inappropriate classroom behavior.

Friends, Acquaintances, and Peer Acceptance

The impact that friendships have on children's school adjustment may result from the uniqueness of the friendship relationship compared to children's other social relationships. A great deal of research has been devoted to identifying differences between children's interactions with acquaintances versus friends. Evidence from this body of work suggests that friends feel a sense of responsibility for one another's needs, that they assist each other in meeting those needs, and that they expect no repayment of the assistance they provide to their friend. In contrast, acquaintances tend to feel less responsibility for one another and are more likely to distinguish the circumstances under which they will provide support to each other. In a comprehensive meta-analysis of studies comparing friends and nonfriends, Andrew Newcomb and Catherine Bagwell concluded that friends engage in more frequent positive interactions, including talking, cooperation, and positive affect, than do peers not identified as friends. Friends are also more similar behaviorally to one another, more egalitarian, more loyal to one another, and less likely to assert dominance over one another than are children who are simply acquaintances. These characteristics are presumably a consequence of friends' greater proximity, heightened mutual interest, and intense concern for one another, and they point to the unique affiliative bond that friends share.

A particularly noteworthy behavioral domain in which friends differ from acquaintances is conflict management. Although friends engage in conflict at rates similar to those of nonfriends, friends are distinguished from nonfriends in their conflict resolution efforts. For example, Willard Hartup and his colleagues found that, compared with conflicts between children who were not friends, conflicts between (4-year-old) friends were less heated, were more likely to be resolved by both partners disengaging from the conflict, were more likely to end in compromise, and were more likely to be followed by continued interaction. The authors suggest that because friendships are founded on emotional commitments, children have a lot at stake in their friendships, and failing to resolve conflict puts the friendship at risk. Consequently, children appear to be particularly motivated to reduce conflict with their friends in order to maintain the relationship. This evidence joins with other research documenting differences in the behavioral

qualities of friendship and children's interactions with acquaintances to suggest that friendships offer children unique experiences, provide distinct developmental resources, and serve different functions than do children's other relationships.

Friendships have also been distinguished from children's social status, or level of acceptance, in the larger peer group. Acceptance refers to being generally well-liked by a group of peers, rather than participating in a specific, close dyadic relationship with one other individual. Research with school-age children and adolescents suggests that acceptance and friendship are unique but related domains of children's peer relationships. For example, in a study examining both friendship status and peer acceptance in early childhood, Ladd found that children who formed new friendships in their kindergarten classroom experienced improvements in school performance over the course of the school year. However, even after taking into account children's friendship status, peer rejection predicted less favorable attitudes toward school, greater school avoidance, and lower levels of academic performance at the end of the school year. More recently, Ladd and Wendy Troop-Gordon found that children who were friendless in first grade had more internalizing adjustment problems and reported being more lonely at school in fourth grade than children with friends. Moreover, the connection between being friendless and children's internalizing problems held true even after taking into account children's chronic peer rejection. Thus, it appears that being accepted by peers and having friends may provide children with different developmental opportunities and may have different connections to children's adjustment in school.

At the same time, however, popularity with peers appears to overlap with the development of friendships. In their summary of research on connections between children's acceptance among peers and participation in reciprocated friendships, Willard Hartup and Nan Stevens concluded that friendship is a positive correlate of social competence for preschool children. Consistent with this view, Brian Vaughn reported that the number of reciprocated friendships enjoyed by preschool children was a positive and significant correlate of overall social competence scores. One way that peer acceptance appears to influence friendships is by determining the amount of choice that children have in friends. Those children who are more popular tend to have more friends, engage in

more cooperative activities, and display more social conversation than children who are socially rejected or neglected. At the same time, however, being well-liked by peers does not guarantee that a child will have a specific friendship, nor does being rejected by one's peer group preclude a child from having a friend. A recent study of second and third graders found that 39% of children rejected by their peer group had at least one mutual friend in that group and that 31% of popular children did not have a reciprocated friendship.

Although there is some question as to when children form friendships, evidence suggests that children begin to discriminate among peer partners and form preferences for particular playmates within their peer groups as early as toddlerhood. Children as young as 30 to 73 months of age (nominal "preschool" ages) have been confirmed to show preferences for specific peers in their day care and preschool groups. These early friendship preferences manifest themselves by the maintenance of close proximity and frequency of interaction between two children. By 36 to 48 months, over half of all children have reciprocated friendships, and many of these friendships are stable over time. Preschool friendship preferences can be reliably assessed using a sociometric choice task, a procedure that asks children to identify their most preferred playmates. Evidence suggests that these early friendships may be differentiated from other peer relationships by the amount of time children spend in reciprocal and complementary interaction.

Friendships and Childhood Development

Age plays a major role in defining the specific behavioral qualities that distinguish children's friendships from other peer relationships and in shaping expectations for interpersonal behavior within friendships. Based on well-defined physiological, cognitive, emotional, and social changes, development during childhood is divided into three major periods: early childhood (3–7), middle childhood (8–12), and adolescence (13–18). Throughout these periods of development, friendships are characterized by reciprocities, mutual liking/attraction, and by affection and having fun together. However, there are marked qualitative differences in children's friendships during different age periods, and the behavioral processes involved in the formation and maintenance of friendships change as children develop. Consequently, friendship interaction during any given developmental period has a characteristic structure and content that give it a distinct signature or theme. The themes of each period and their developmental progression are normative in that they reflect children's attempts to adapt to the demands of their social-ecological niche.

Early Childhood

During early childhood, friendships are defined by the theme of playmate. Young children place a premium on a child's potential as a playmate, both in their descriptions of actual friendships and in their beliefs about friendships in general. Consequently, in this developmental period, friendships may be identified by children's maintenance of close proximity, engagement in mutually interesting activities, and time spent together. The level of enjoyment and satisfaction children experience with playmates depends almost completely on the level of coordination they achieve. Coordination refers to the extent to which two children are able to fit together their separate actions into jointly produced discussions or activities. Coordination is easier to achieve when children share similar interests and behavior patterns. For this reason, similarity is a key factor in young children's friendship formation. However, it is not the specific nature of their similarities that interest young children, but rather the mere presence of commonalities. In their effort to establish commonalities, a good deal of young children's friendship conversation involves social comparison processes. Once friendships are formed on the basis of commonalities, efforts to maintain those relationships are motivated by the desire to achieve coordination of play. Thus, the interactive emphasis of young friends centers on play negotiation, emotion regulation, and conflict management.

Middle Childhood

As children transition from early childhood to middle childhood, their conceptions of friendship change from a self-centered view of what a friend can do for them as an exciting playmate to a more balanced perception of friendship, involving reciprocal and mutually satisfying interactive exchanges. In addition, children move developmentally from an emphasis on friendship being a momentary act between individuals to a focus

on the enduring affective nature of the relationship. Consequently, during middle childhood, children's friendships have been characterized by the theme of companionship. During this period, friendships become more stable and are more often reciprocated. Also by middle childhood, as a function of growing interpersonal awareness, the basis of friendships centers more on shared norms and personal qualities, as opposed to common interests. The behavioral processes that are salient to friendship also change during middle childhood. For example, fantasy play among friends appears to decline dramatically from preschool to middle childhood, whereas animated conversation, games, and contests become more common. In addition, during middle childhood, the content of conversations between friends begins to focus more on sharing intimate information about the self, and children come to expect that friendship creates an obligation for mutual aid or support when needed or requested by a friend.

Adolescence

In adolescence, friendships depend on and manifest themselves in intimate, dyadic exchanges that feature openness, honesty, and affection. Evidence suggests that as adolescents become preoccupied with concerns about developing autonomy and self-governance, they begin to rely more on friends for intimacy and support. Accordingly, the theme of friendships during this developmental period is intimacy. Friendships serve the function of helping adolescents to achieve individual identity and self-understanding. This role is evident in the expectations that adolescents espouse about friendships, which focus on similarities in interests and personalities, and processes of intimacy and validation. Likewise, the interactive emphasis of adolescents' friendships center on self-disclosure, positive gossip, and shared intimacy. During adolescence, friendships become the primary social relationships in which young people share their confidences. Emotional support and autonomy are also seen as essential elements of friendship among adolescents. However, compared to previous ages, adolescents are less preoccupied with what benefits they derive from their friendships and are more conscientious of their friends' needs.

Negative Effects

Although it is clear that friendships typically feature reciprocity, loyalty, shared positive affect, and

companionship at all ages, it is also important to note that friendships can serve as contexts for less-amicable social processes. As previously indicated, conflict is prevalent in interactions between friends, and although friends typically manage conflict in more optimal ways than do children who are not friends, the fact remains that excessive interpersonal conflict is predictive of adjustment problems. Friendships can also serve as the setting for harmful interpersonal processes, such as coercion, jealousy, and betrayal. Moreover, children may form friendships with children who demonstrate antisocial characteristics. Such friends, in turn, can pressure children to engage in behavior they might not otherwise consider. In addition, some friendships can magnify the child's own antisocial tendencies, or they may lead to bully-victim relationships. For these reasons it is important for parents and teachers to consider the quality of children's friendships and to give attention to whom children form friendships with.

Implications

Research clearly indicates that most children have at least one friend. Moreover, empirical evidence points to the significant role that friends play in children's adjustment to school and academic performance. Friendships can be distinguished from other social relationships in which children are involved. Friends engage in interactions that are qualitatively different from those of children who are not friends. Children who are friends communicate clearly, self-disclose more often, and resolve conflicts in ways that enhance the likelihood that their relationship will continue. Friendships also have been distinguished from children's social acceptance in their peer group. A significant portion of children who are well-liked by their peer group do not have a specific friend, and a substantial number of children who are rejected by peers do have a friend. Characteristics of children's friendships change with age. As children grow older, their thinking about friendship progresses from the concrete to the abstract, and this change is manifested in their interactions with friends. Specifically, over time, children's friendships become more stable, demonstrate more reciprocal altruism, and consist of more shared intimate personal knowledge. Recent research also indicates that friendships can have deleterious as well as constructive effects on children's adjustment and can involve both positive and supportive

interactions as well as conflictual and stressful interactions. Moreover, who a child chooses as friends appears to be as important as whether a child has friends or not. The implications of this information concerning children's friendships are complex and important for both educational policy and classroom practices.

The young do not know enough to be prudent, and therefore they attempt the impossible—and achieve it, generation after generation.

—Pearl S. Buck

GANGS

The topic of gangs has generated extensive literature and social action. Questions over both definitions and solutions typify gang research, policy, and intervention. Law enforcement efforts at containing gangs date back to colonial America. In turn, modern empirical research into gangs began in the late 1920s. Despite the longevity of gangs as a social problem, there is still ongoing debate concerning the composition of gangs, their behavioral dynamics, and the most effective gang reduction strategies.

This entry discusses the definitions of gangs, the factors that cause them, gang typology, and the dynamics of gang membership. This discussion is followed by an examination of the various types of gangs. Finally, differing anti-gang strategies and problem-solving approaches are explored.

Differing Definitions

Probably the biggest challenge to researchers, anti-gang practitioners, and policy makers alike is that there is no standard or widely accepted definition of the word *gang*. Because there are so many competing definitions, any discussion or collaboration between different groups suffers; there is no common vocabulary. Communication is hindered by muddled comparisons and lack of terminological clarity. This confusion in definitions and concepts contributes to greater problems in trying to understand the prolific growth of gangs from the 1990s onward. Furthermore, this confusion contributes to the difficulty building consensus around the most effective anti-gang strategies. This definitional problem raises the question of which comes first: Does gang membership push youth into criminal activity, or does criminal activity push youth into gang membership? Because the concepts underlying membership in gangs are similar to the concepts underlying membership in other social organizations, the result is contradictory definitions and conflicting problem-solving approaches.

Every group involved in solving the gang "problem" agrees that there is a need for a universally accepted definition that would serve as a basis for action, policy, and research. However, this is where agreement ends. Depending on the perspective, the definition of gangs and gang membership differs.

Definitions derived from criminal justice and law enforcement diverge from those utilized in the social sciences and comprehensive academic approach. Although there is some strong overlap between these definitions, each is distinct. Criminal justice definitions focus on violations of the law. Academic definitions focus on the structure and motivation behind gang behavior. Additionally, there is frequently little agreement

on definitions at the federal, state, and local levels of government; laws and policies developed at different levels conflict.

Criminal Justice and Law Enforcement

According to criminal justice professionals, a *gang* is any group that gathers on an ongoing basis to engage in antisocial or criminal activities. Gang members identify with one another based on geographical location, clothing colors, symbols, and names. They communicate their gang affiliation through hand signs and graffiti. Law-breaking activities enhance the gang's credibility, create fear in the community, and may provide an ongoing source of income for the gang and its members. The magic number of individuals necessary to constitute a gang is universally acknowledged to be three. Nevertheless, rigid definitions such as these frequently omit information needed to understand the phenomenon of gang membership and guide both policy and research.

Academics and Social Sciences

Academic definitions are aimed at understanding and communicating information regarding the structure and motivation of gangs. Gangs are viewed as loosely organized groups of individuals who assemble together for social and criminal purposes. Membership in a gang fulfills complex and interrelated psychological needs. Gangs proliferate as a result of social conditions and cultural pressures.

Comprehensive Definition

Gangs can best be defined as any type of ongoing group or organization of three or more individuals, usually adolescents and young adults, who interact frequently with each other and are recurrently and deliberately involved in violence and criminal activity, individually and collectively. This criminal activity includes fights, intimidation, and threats. Gangs may be formal or informal in nature, but all generally form an allegiance for a common purpose. Most notably they share a collective identity that is usually expressed through a gang name as well as identifying signs or symbols. Each gang typically identifies with, and claims control over, certain "turf" or territory in a community—which is not limited to geography but can mean other individuals, objects, or businesses.

Gang membership generally forms along ethnic and socioeconomic boundaries. Long associated with urban settings, gangs have migrated to suburban and rural settings as well. Gangs are now found in all types of communities and socioeconomic strata.

Gangs are loosely controlled by a leader or leaders who direct the gang for their own benefit as well as for the benefit of their followers. Usually, a gang's leaders are characterized by their desire to maintain a strong or "bad" reputation, their need for respect, and their drive to respond to actual or perceived disrespect with acts of retaliation or revenge. A gang's reputation is based on both the actions and influences of its individual members as well as the gang as a collective.

Much debate focuses on the extent of gang organization, structure, and cohesion. One position, held by many in the criminal justice system, maintains that gangs are extremely cohesive and organized with rules, rituals, and stratified social roles. There are dire warnings about the increased migration of street gangs into legitimate business and even politics. The opposite position, predominant among social scientists and gang interventionists, holds that gangs are informal, constantly shifting groups that lack any authentic organization. However, research and practice reveal that both cohesiveness and structure vary with the gang and the setting. Most street gangs are loosely organized, with several members who serve in leadership roles commonly referred to as "shot callers." Membership fluctuates and gang members possess varying degrees of commitment and loyalty to the gang. Gang cohesiveness and feelings of commitment are always highest when the gang is challenged by other gangs or by outsiders—in particular, law enforcement. Some gangs are extremely organized and cohesive, but most remain transient, flexible, and fragmented. Most importantly, there is almost never a central gang authority coordinating gang structure or movement.

Changes in Gangs

Gangs are no longer an exclusively urban phenomenon. Although they remain firmly anchored in urban settings, their presence has spread to rural environments, and many gangs now have transnational affiliation. Additionally, gangs have "aged." No longer restricted to juveniles, their upper age limits for membership have increased, with individuals remaining in gangs for longer time periods. Moreover, gangs are growing more intergenerational. Many possess third and fourth

generation members, the great-grandchildren of "original" gang members. In another shift in exclusivity, gang membership is now no longer limited to males. Additionally, the division between street and prison gangs continues to weaken, with growing integration between formerly separate entities.

Types of Gangs

Deborah Prothrow-Stith offered a typology that describes three major gang types:

1. *Scavenger gangs* are best described as underachiever gangs. These groups are loosely organized, with activities that are largely impulsive and unplanned. Their leadership may shift on a frequent basis. In gang culture, scavenger gangs occupy the lowest status, typified by unsuccessful criminal efforts that are derided by other gangs. Alternatively, these groups can be viewed as "gangs in the making." In fact, many evolve into the more structured territorial gangs.

2. *Territorial gangs* are organized around territory or turf. These are the stereotypical gangs associated with Los Angeles and other urban settings. Their membership is usually well organized. These gangs practice complex, formal initiation rites for new members as well as other ceremonies, rituals, and customs that differentiate members from outsiders. Gang membership is a source of pride, status, and power. The major activity of these gangs is fighting—the crossing of territory or turf lines is used as an ongoing excuse to brawl. These gangs may engage in drug dealing, but only as a secondary activity. Their primary activities remain social and criminal. The drug dealing that occurs is usually a matter of economic survival, not a result of a complex marketing or distribution cartel.

3. *Corporate gangs* are highly structured, criminal entities organized around drug trafficking and profit-making. Their members fulfill the roles and responsibilities of traditional gangsters, sharing characteristics with organized crime more than with inchoate street gangs. These gangs enforce strict codes of secrecy and discipline, with severe consequences for transgression. Their membership is highly intelligent and their leadership, akin to any corporate entity, exhibits sophisticated strategic planning as well as financial and personnel management.

Description and Causes

Gang Member Profile

The mystique of gangs has generated myths concerning the "typical" gang member. In truth, the typical gang member may be uneducated but above average in intelligence. Most gang members exhibit sophisticated street survival skills, and many are accomplished in the art of manipulation. Additionally, they follow a strict code of conduct as defined by the gang. Each gang member is concerned with proving their worth, being recognized for their work, and establishing a reputation for being "bad." They are loyal to all other gang members, their loyalty bordering on a family-like affinity, and they are very protective of their turf. This does not minimize the antisocial, destructive core of their behavior but rather places it within context.

Etiology

Gangs find their genesis in the sociological and economical conditions that foster and reinforce individual and psychological vulnerabilities. The three predominant, interrelated factors promoting the existence of gangs are family dysfunction, community violence, and extreme poverty. Children growing up in gang-saturated and economically deprived urban "hot spots" often perceive few alternatives to the gang lifestyles. However, as gangs have spread to rural, nonurban environments, the common denominator in their continued existence and further proliferation is family disintegration. The gang replaces the family as the new source of attachment, security, and stability. By fulfilling these basic human needs, gangs solidify their control over individual gang members.

Characteristically, gang members come from uninvolved or dysfunctional families. Their family relationships are unstable, and many have parents or siblings who encounter ongoing problems with substance abuse. Immediate and extended family members are often involved in gang or criminal activities. Many youth who join gangs have been physically, emotionally, or sexually abused or have suffered extreme child neglect. Gang membership appears as an attractive alternative to the child welfare system and likely placement in foster care. Equally dangerous enticements arise when parents, older siblings, or other relatives have been, or continue to be, gang members. These family members embody role models for young individuals to emulate.

All individuals possess needs for feelings of self-worth, identity, acceptance, recognition, purpose, and

security. Gangs often supply what traditional systems have failed to provide. Youth who are frequently poor, uneducated, and adrift experience the gang "surrogate family" as a source of security and identity in the absence of other support systems. The gang offers acceptance and structure, which—when contrasted with the instability of family life—presents an alluring substitute. Psychological attachment paired with social and environmental factors provides strength to the dynamics of gang membership.

Gang youth believe, often defensively, that they will never succeed in conventional society. Disenfranchised, they lack even the most basic employment skills, such as maintaining a proper appearance or demeanor. However, more fundamentally, gang members feel disconnected from mainstream social and cultural values. They do not perceive the future as filled with opportunities. Additionally, individuals believe that illegal activities provide the only means by which to earn money easily without working.

Gang membership offers a sense of empowerment and status. Members who may have dropped out of school and are unemployed obtain a sense of purpose, identity, and occasionally even ad hoc leadership training. For many individuals, this constitutes a heady mixture of excitement, power, and success. This is integrated with a need for acceptance that may also be fueled by intimidation from others. Many join gangs out of the need to belong or feel accepted by others; young women may join because they have boyfriends in a gang. In more severe circumstances, an individual may join a gang as a response to violent peer pressure from within the gang or as a form of protection from violent threats from rival gang members.

For many in gangs, there is a sense of fatalism that masks their feelings of aimlessness and lack of control. This fatalism often translates to a preoccupation with death and how one dies. Many gang members report dreaming of their deaths, how they wish their funerals be conducted, and their despair at not living to see their children grow up. This morbid preoccupation is a motivating factor in the contradiction of having children while, at the same time, participating in the acts of violence that are hallmarks of gang membership.

Dynamics of Gang Membership

The evolutionary process that brings a child or youth from innocence to gang membership involves a gradual yet powerful set of forces. Gangs work on recruiting vulnerable youth and monitoring their progress. These recruits are slowly allowed to associate with the gang. When gang leadership determines that the youth is ready for full membership, elaborate initiation rituals are imposed to test loyalty, extinguish individuality, and promote service to the gang. The most common initiation ritual of being "jumped in" includes being beaten, humiliated, and, if the gang member is female, raped by multiple gang members. Occasionally, a desirable member is "courted in" and proffered regular gang membership without any initiation ritual.

Gang Membership Typology

Gang membership can best be divided into five major categories:

1. *Hard-core* gang members compose approximately 10% of the gang population. Hard-core gangsters usually have been gang members for the longest time periods and are influential in directing gang activities. They are frequently in and out of jail, unemployed, and using and selling drugs.

2. *Regular* gang members are the younger gang population, ranging in age from 14 to 20 years. Having been initiated or "jumped" into the gang, they back up hard-core gang members in word and action. Those with juvenile status often act as lead participants in gang activities because it is believed that the juvenile justice system will be less punitive. In this way, their commission of crime protects older gang members. In many cases, they consider themselves to be veritable hard-core gangsters "in training."

3. *Associate* gang members can be characterized as ambivalent concerning their gang status. They believe there is no way to exit the gang. These individuals exhibit a certain degree of moral awareness as to the cost of their involvement. However, due to a combination of intimidation, fear, and loyalty, they remain unable to renounce membership and unresponsive to intervention efforts.

4. *Wannabe* gang members vary in age, but generally range from 10 to 13 years. Anecdotal evidence suggests even younger children are increasingly aware of and attracted to gangs. These individuals are not formal gang members but act as if they are in the gang. They dress in gang attire, spend time with gang members, and tag (i.e., write graffiti associated with the gang on surfaces visible to the public).

5. *Potentials* are individuals who live in or close to areas populated by active gangs. These youth may have a family member who already belongs to a gang. However, individuals in this category perceive that there are alternatives, such as school, which can be accessed in order to avoid gang membership altogether.

Consequences of Gang Membership

The price of gang membership is high, and consequences are extreme. From the onset of membership, violence is a hallmark of life in the gang. Initiation rituals involve several forms of physical force, including being "jumped in." This involves a group of gang members physically beating the youth. In addition to this beating, there is typically a requirement that the individual commit serious criminal and violent acts to prove his or her loyalty. Once a youth is initiated, gang membership invariably guarantees a criminal record along with the physical risks associated with ongoing violent activities. It is also important to remember that labeling an individual a gang member is a stigmatizing event. In general, mainstream culture is extremely judgmental, and many believe that once an individual belongs to a gang, that membership is retained for life.

Usually, gangs depend on their youngest regular members to carry out the most serious offenses in the mistaken belief that juveniles receive more lenient treatment when found guilty of a crime. Instead, following the passage of anti-gang laws in several states, this is no longer the case. Youth are now legally criminalized at progressively younger ages. Correspondingly, youth are now socially assigned a career of gang membership at earlier ages. This phenomenon is reflected in both gang recruitment efforts and gang prevention programs, both of which are aimed at younger-aged children.

Violence

There is a great deal of disagreement in the theoretical literature about the association between gangs and violence. However, although reports on the day-to-day existence of gangs reveal that violence is not perpetual, statistics point to a high association between gangs and ongoing violent crime.

Dynamics of Gang Violence

The potential for gang violence occurs most frequently during gatherings in which gang members enter the turf of a rival gang. It is an oversimplification to assume that this occurs only on certain streets or in certain neighborhoods under the control of a gang. In reality, such "turf violations" may also occur in regional centers for sports, recreation (parks), entertainment (movie theaters and concert venues), and schools. Any bus stop, street, or freeway is also "fair game" in terms of gang violence if a gang crosses turf lines.

Potential gang violence may also erupt over the issue of "disrespect," which assumes many forms. One common form of disrespect involves tagging and occurs when one gang crosses out the graffiti of another gang. Menacing looks or stares, "throwing" gang signs, hand signals, and other nonverbal confrontations are also invitations to violence. Verbal precursors include talking trash, ragging on, bragging, and calling out gang names as well as taunts or threats. Other forms of intimidation, such as stepping on toes, bumping, or other "accidental" or intentional physical encounters can spark an incident. Though childish in quality, the smallest incident often can be perceived as disrespectful and constitutes a virtual call to arms. Indeed, the randomness of gang violence is exacerbated by the impulsivity with which gang members determine what actions are disrespectful as well as what to overlook.

Guns

Gang involvement or membership is strongly correlated with gun possession and use. This is due to combined factors: the growing availability of weapons, intimidation by other gangs, the need for self-protection, and the quest for status and identity. However, the power and protection provided by gun possession also pose an added threat: Gang members are at greater risk for being harmed or killed by someone with a weapon.

Increasingly, gangs acquire and use automatic and semiautomatic weapons. These are employed in drive-by shootings, as gang members in a motor vehicle "drive by" and shoot at rival gang members. The use of such lethal weapons has altered gang activity, rendering it more deadly. Painful and unanticipated losses have resulted from this lethality, particularly when gang members miss their intended targets and instead hit uninvolved community members, including children.

Drugs

Both law enforcement and social researchers have sharpened their focus on drugs as a mainstay of gang

activity, revenue, and power. There are few data on the actual relationship between drugs and gangs. Long-term involvement in drug sales and distribution entails secrecy and cohesion not traditionally associated with gang organization and membership. Nevertheless, gangs may be involved in ongoing, albeit erratic, drug usage and dealing. There is considerable disagreement about whether or not drug dealing is separate or part of an ongoing gang business enterprise. Many law enforcement professionals insist that gangs are businesses with elaborate systems for managing cash flow, laundering money, collecting "taxes," and conducting drug wars. In reality, although some gang homicides arise from disputes over drugs, most violent incidents involving gang members evolve from fights over turf, status, and revenge. Also, most gangs are not akin to the traditional tightly organized, drug distribution cartels. Subgroups within gangs deal drugs, with varying degrees of organization and success. Although the extent of involvement varies, it is reasonable to conclude that drugs are an ongoing and growing component of gang life.

Problem-Solving Approaches

Four major approaches underlie most anti-gang strategy:

1. Suppression
2. Prevention
3. Intervention
4. Comprehensive approach

Overall, the general solution to gang membership and its associated criminal activity involves the use of multifaceted and comprehensive anti-gang programs. These programs include alternatives for at-risk youth, strong law enforcement, and committed community leaders all collaborating to combat the gang culture and offer youth options. However, before the comprehensive approach is examined further, each of the other three anti-gang strategies and the impact each has on reducing gang membership and activity are discussed.

Suppression

The goal of suppression is to reduce gang activity. Based on traditional criminal justice methods, its practitioners, usually comprising law enforcement

officers, probation officers, and prosecutors, use arrest and incarceration to control gang violence and suppress criminal activity. Suppression practitioners enact gang injunctions to keep identified gang members from assembling in public. They also utilize vertical prosecution along with sentencing enhancements for gang involvement, gang membership, or both.

Prevention

Prevention is designed to identify high-risk children and youth who have *not yet* joined a gang and to preclude their joining a gang or participating in gang activity. Primary prevention is aimed at broad populations, for example, children from birth to 5 years old who are growing up in a gang-saturated neighborhood. On the other hand, tertiary prevention programs specifically focus on youth who are gang potentials or gang associates.

Currently, prevention efforts concentrate on middle school youth, with some additional programs developed for elementary school children. Strategies include offering mentoring and academic support as well as activities to initiate and enhance parental involvement. Additionally, sports and recreation as alternatives have been developed in community settings.

When a setting is *not* in crisis, prevention programs command the greatest attention. Once gang crime develops, suppression assumes the predominant role in reducing gang activity—with the sentiment that prevention can be practiced once neighborhood safety is reestablished.

Intervention

Gang intervention encompasses a broad range of actions and strategies designed to constructively influence and divert either individual gang members or one or more gangs in a locale or setting. It is aimed at individuals or neighborhoods that have progressed past the point of being labeled "at-risk."

Gang intervention strategies are limitless in design and focus; some strategies involve individuals who are currently active gang members whereas other interventions focus on individuals reentering society after release from incarceration. Individual intervention includes tutoring, job training, tattoo removal, counseling, assistance with substance abuse, legal aid, and using both community- and faith-based groups to convince gang members to leave the gang.

Group gang intervention brings rival gangs to the negotiation table by employing former gang members as street "interventionists." These street workers engage in dialogue and relationship building that may entail dispute mediation or conflict transformation through the construction of gang truces or peace treaties. Also, when death occurs due to gang violence, gang interventionists often raise money to help families with funeral expenses and concurrently work to curb retaliation and further violence.

Comprehensive Approach

The current cynosure of anti-gang strategy is a combination of suppression, prevention, and intervention known as the *comprehensive approach.* This strategy entails a dynamic collaboration between criminal justice and social service professionals, academicians along with mental health facilities, schools, and community- and faith-based organizations. Equal weight is assigned to community mobilization, workplace development, and law enforcement. Extensive services to all sectors are offered. This approach is potentially effective but also very costly.

Future Directions

The topic of gangs remains dynamic and changing. Both gangs and the research and policy directed toward them are constantly evolving. It is clear that the existence of gangs continues to be traced to a combination of psychological, cultural, and social factors. In recent developments, however, their activities involve increasing levels of violence, diverse groups, and new, nonurban settings. What is most striking about gangs is that they continue to exist and remain resistant to traditional anti-gang strategies. Challenges endure in terms of future gang policy, interdiction, and research. The questions of what a gang is, how membership and organization are structured, and which problem-solving approaches are the most effective are still open to debate.

GENDER

The word *gender* originally existed as a grammatical category stemming from the Latin word *genus* and can be translated as "kind" or "sort." Genders were known as classes of nouns reflected in behavior of associated words. In some languages, gender is central and adjectives and verbs show gender agreement; in other languages, adverbs, numerals, and other parts of speech agree. In some languages, gender is absent. Stemming from linguistics in which gender referred to feminine and masculine forms within language, gender conveyed strong associations about the role of society in distinguishing words coded as male and female.

During the 1960s, feminist scholars extended the cultural constructions of gendered language to adopt the concept of gender to distinguish cultural characteristics associated with masculinity and femininity from biological features distinct to males and females, such as male and female chromosomes, hormones, and internal and external reproductive organs. The use of the word *gender* rather than *sex* was used to repudiate beliefs that biology determined male and female behavior, including stereotypical beliefs about female inferiority. Gender was distinguished as the cultural part of being a man or a woman, and being masculine or feminine was no longer connected with biological sex but described as a culturally variable characteristic.

Now, in current speech, *gender* has almost completely replaced *sex* except when referring to sexuality. When asking if a person is a man or a woman, it is customary to ask for "gender" rather than "sex." In fact, many psychologists use the term *sex*

differences and *gender differences* interchangeably. However, it is important to clearly distinguish the terms *sex* and *gender* when discussing social psychology. Many influential researchers in the field use *sex* to refer to the binary categories of male and female and *gender* to refer to the attributes associated with the two sexes, including gender roles and gender stereotypes. It is important to note that this convention is not universally accepted, and often researchers do not distinguish between sex and gender because of different philosophical viewpoints.

The importance of studying gender as a social category is to provide meaningful explanations of historical and cultural relationships between women and men and to better understand social organization as it relates to gender, including gender expectations, educational and professional opportunities, and power relations. In U.S. society, there are still large discrepancies between men and women in social roles, earning power, and occupational status. In families where both parents work full-time, the majority of household chores and child care is the responsibility of the woman. The income of the average working woman is significantly less than that of the average working man. From 1951 to 1999, 90% of university professors in chemistry, physics, mathematics, and engineering were men. In the United States, most positions of political power are held by men.

What causes these differences? There are many possible social explanations, including the notion that, in general, parents, teachers, and society expect and encourage different things from girls and boys, men and women. Gender stereotyping is pervasive: Males are more widely believed to be dominant, independent, aggressive, and achievement-oriented, whereas females are generally believed to be nurturing, affiliative, less esteemed, and more helpful in times of distress. Historically women have been oppressed and have not been offered equal opportunities. Before 1928, women could not vote. Women were less likely to be admitted to institutions of higher learning even when their qualifications were equal to those of male applicants. In fact, until 1969 many private colleges and universities did not admit women. In the past 50 years there have been some changes in social roles and economic and political status of women due to legislation and efforts to abolish various inequities; however, in most settings gender stereotypes persist and provide justification for the existing social arrangement of males as dominant and women as subordinate.

Measuring Gender Differences

To study differences between men and women, researchers must be able to measure them, but measuring psychological characteristics is difficult because they cannot be seen directly and are inferred from observable behaviors. There is no general agreement on the most appropriate instruments or methods for measuring psychological or behavioral differences. Research on gender differences is exceedingly complex because individuals have their own beliefs about gender and these widely held beliefs, or stereotypes, provide a lens through which researchers view behaviors and research findings.

In *The Psychology of Sex Differences* Eleanor Maccoby and Carol Jacklin outlined four major problems associated with studying sex differences:

1. Overreporting of significant differences
2. Influences of stereotypes on perceptions of researchers and participants
3. Sex differences being situation dependent
4. Disagreement in results using different methods

First, there is an overreporting of significant sex differences because there is a tendency to publish studies in which a sex difference is reported, whereas studies not showing significant sex differences go unpublished. Second, people tend to see what they expect to see based on personal beliefs, assumptions, and experiences. For example, a father may report his son plays rough because that is what he expects boys to do. The next problem with studying sex differences is the possibility that a sex difference is dependent on a situation as is represented in the research on achievement motivation. In certain situations girls show more achievement motivation than boys, but in other situations the sex difference disappears or reverses. The final problem is in situations where different methodologies produce conflicting results. An example is the study of anxiety and fearfulness. On self-report measures girls indicate more anxiety and fearfulness than boys, but based on teacher ratings of behavioral observations, there is no sex difference.

Although there are problems confounding the study of differences between males and females, Maccoby and Jacklin site evidence supporting significant gender differences in aggression, juvenile play behavior, and specific cognitive abilities, including visuospatial ability, mathematical ability, and verbal ability. Later findings suggest gender differences exist only in

specific subcategories of the specific abilities. The largest gender differences appear in mental rotation tasks as early as 4 years of age. Additionally, there is evidence to support gender differences in personality traits such as nurturing tendencies, dominance assertion, and activity level in children.

Gender Differences in Cognition

The gender differences in general intelligence and specific abilities have been widely studied, producing a large amount of information about female and male cognitive abilities. Most general intelligence measures show insignificant differences between the sexes. However, some subtests of the Wechsler intelligence scales show moderate differences favoring females on the symbol/coding subtest and favoring males on the information and block design subtests. A well-known cognitive difference is on the measures of visuospatial abilities. The largest difference favoring males is on measures of mental rotations. The differences range from small on two-dimensional tasks to large on three-dimensional tasks. The difference in mental rotations is apparent in childhood but seems to increase with age. Spatial perception tasks also show gender differences, with the differences appearing larger in adults than in young people.

Mathematical and verbal ability has also been studied for gender differences. Similar to visuospatial abilities, mathematical abilities vary with age and the type of ability measured. Differences are also dependent on the population studied. Overall difference in mathematical ability is negligible but in the direction of favoring females. However, in older, selected samples, such as college students taking standardized tests such as the Scholastic Aptitude Test (SAT) and the Graduate Record Exam (GRE), differences favor males on problem-solving tasks. Analyses of verbal abilities indicate a slight overall female advantage. When looking at individual tasks, males show a negligible advantage for analogies, and females show a small advantage in measures of speech. Some specific measures of verbal fluency may show larger female advantage, but other verbal abilities show essentially no sex differences.

Gender Differences in Aggression

Findings suggest greater aggression in males than females. These differences are seen in several contexts and across cultures. Males are found to be more aggressive in fantasy, administer more verbal insults, show a greater modeling of aggressive behavior, and self-report aggression to a greater extent than females. Girls are more likely than boys to engage in relational aggression including behaviors such as trying to make others dislike an individual by spreading malicious rumors or ignoring another child when angry.

The reasons behind these differences are unclear. Many scholars suggest a focus on *how* gender works to explain *why* gender works. Next, several theoretical models of gender are presented that stress how gender-related behaviors emerge or are acquired. Three categories of models are described: biological influences on gender differences, early acquisition of gender-related behaviors, and sociological influences on behavioral differences between men and women.

Biological Influences

Biological models of how gender-related behaviors emerge or are acquired argue for genetic, hormonal, and physical factors as determinates of sex differences. These models consider how male/female biological differences influence gender identity and gender roles.

Chromosomes and Hormones

Biological foundations may influence the social and psychological dimensions of being male or female. Humans have 46 chromosome pairs. The chromosome difference of males and females occurs in the 23rd pair. Females have two X chromosomes and males have an X and Y chromosome. In addition to having different chromosomes, males and females experience differing levels of sex hormones. There are two main classes of sex hormones: estrogens, influencing the development of female physical sex characteristics, and androgens, promoting the development of male physical sex characteristics. After the first few weeks of gestation, the Y chromosome in the male embryo triggers the development of testes secreting large amounts of androgens and leading to the development of male sex organs. In females, low levels of androgens allow development of female sex organs. It has been suggested that early androgens might influence later behavior, as seen in increased activity levels among boys.

Recent research suggests gender identity begins to develop at this early stage of embryonic development. Males (an X and Y chromosome) with a rare birth

defect causing ambiguous genitals who are surgically assigned to be female frequently report feeling like boys and may change their gender back to male even without knowledge of their birth history. This issue is complex because although the majority of birth males assigned to be females identified themselves as male, nearly one third of study individuals were well adjusted living as females. The nature versus nurture debate is reified with the question of how much gender identity can be attributed to genetics versus socialization.

Evolutionary Psychology

Evolutionary psychologists argue adaptation during the evolution of humans produced psychological differences between males and females. Because of differing roles in reproduction, males and females faced different pressures to survive. Natural selection favored males with short-term mating strategies because having multiple sex partners improved the likelihood males would pass on their genes. Females who devoted effort to their offspring and chose mates who provided resources and protection were favored by natural selection. Males competed to acquire more resources to access females; therefore, according to evolutionary psychologists, males evolved to be more violent, competitive, and risk taking. These evolutionary differences between males and females explain gender differences in sexual attitudes and behaviors, according to evolutionary psychologists; however, in other areas of psychology, males and females are similar.

Evolutionary psychology is based in speculations about prehistory, and critics claim that there is no evidence for these speculations. Critics additionally point out that people have choices about their behaviors, and thus, prehistoric humans could have changed behaviors that were adaptive to a particular environment. Furthermore, evolutionary views pay little attention to cultural and individual variations in gender differences.

Social Influences in Early Learning

Many social scientists theorize gender-related behaviors and psychological gender differences emerge or are acquired due to social experiences. Within these social theories, perspectives such as psychoanalytic theory, social cognitive theory, cognitive development theory, and gender schema theory emphasize the early acquisition of gender-related behaviors and assume that early learning ultimately accounts for adult gender differences in a wide variety of behaviors.

Psychoanalytic Theory

The psychoanalytic approach seeks to explore a child's gender development from Sigmund Freud's view of the nature of human sexuality. Freud believed that the preschool-age child (3–5 years of age) develops a sexual attraction to the opposite-sex parent. At 5 to 6 years of age, the child experiences anxiety due to this sexual attraction and renounces it and then identifies with the same-sex parent. Unconsciously, when identifying with the same-sex parent, the child adopts that parent's characteristics, therefore developing his or her gender behavior. However, critics argue gender development is not as Freud proposed. More recent studies show children become gender-typed much earlier than age 5 or 6, and they develop masculine or feminine traits even when the same-sex parent is not present.

Social Cognitive Theory

An alternative explanation of how children develop gender-typed behavior is the social cognitive approach. American psychologist Albert Bandura emphasized the links between cognitive processes and environment and behavior. His research focused on imitation or modeling in which learning occurs through observing what others do. In this theory, a child develops gender-typed behavior through the rewards and punishments children experience for gender-appropriate and gender-inappropriate behavior. There are socialization pressures to behave consistent with stereotypical gender norms, and these norms are gradually internalized and displayed. Children learn about gender norms from their parents, other adults in their neighborhood and in the media, and from their peers.

Parental Influences. Gender development in children is influenced by parents' actions and examples. Parents often use rewards and punishments to teach daughters to be feminine and sons to be masculine. Mothers are usually charged with the role of nurturer; however, fathers appear to play an important part in gender-role development. Fathers are more likely than mothers to act differently toward sons and daughters, contributing more to gender-role differences. However, there is

variation in the amount of gender-role pressure on individual children. Some parents encourage girls to be more nurturing and emotional than boys, for example, by reinforcing gender stereotypes in play by giving girls dolls to play with while engaging in aggressive play with their sons. Other parents make few distinctions between boys and girls. These parenting differences, in conjunction with variation in individual children's temperaments, produce a range of gender-role behaviors within children of the same sex.

Peer Influences. Although parents provide the earliest modeling of gender roles, peers also respond to and model masculine and feminine behavior, often rejecting children who display actions characteristic of the other gender. There is evidence boys experience greater pressure to conform to gender-role stereotypes than girls.

There is increasing attention to the importance of gender in peer relations. Maccoby studied the role of gender in children's peer groups. Beginning in the preschool years, children show a preference for spending time with same-sex playmates. This preference continues from 4 to 12 years of age, and during elementary school, children spend a majority of their free time with children of their own sex. Children show own-sex favoritism, but Maccoby found that only a few behaviors are differentiated by sex: Boys and girls showed differences in their playmate preferences, rough-and-tumble play, direct aggression, and themes enacted in pretend play.

Cognitive Development Theory

Cognitive development theory focuses on the personal self rather than the social self and emphasizes the active construction of individual understandings of gender. Developmental psychologists believe the goal of social development is to cultivate a self-concept distinct from others yet connected to others. From infancy to adolescence, individuals form an identity based on their psychological self and their social self. The psychological self is based on an individual's knowledge and belief in their unique characteristics, abilities, and preferences. The social self is how the individual identifies with parents, peers, and social groups. Developmental psychology maintains gender categories are meaningful for young children.

Applying the conservation and categorization skills identified by Piaget, cognitive development theory describes three levels of children's developing

understanding: awareness, identification, and constancy. First, children must develop an awareness of gender categories. Most children can correctly label gender categories shortly after their second birthday, and nearly all children can sort photos based on gender by the time they are 3 years old. In the identification stage, children can label their own gender. Findings suggest children can identify their own gender between the ages of 2 and 3 years. Lawrence Kohlberg proposed gender-typed behavior only occurs after children develop constancy, the learning that a social category is not changeable. Kohlberg suggests constancy develops by the identification of group membership, stability of group membership over time, and consistency of group membership even if there are changes in an individual's appearance or context. Therefore, if children understand the unchanging nature of being a boy or a girl, they develop gender identity and seek information about appropriate behaviors for their sex and behave according to their findings.

However, recent evidence has shown children do not develop gender constancy until they are approximately 6 or 7 years old. Gender preferences for toys, clothes, and games are often evidenced before this time. So, contrary to Kohlberg's assertions, critics argue gender-typed behavior does not appear to depend on gender constancy.

Gender Schema Theory

Similar to cognitive development theory, gender schema theory asserts individuals construct their own ideas of gender; however, gender schema theory does not include gender constancy as necessary before gender-typing of behaviors and preferences begins. Children gradually develop *schemas*, cognitive structures that are networks of associations guiding an individual's perceptions. A *gender schema* is how a child organizes the world in terms of female and male and defines what is gender-appropriate and gender-inappropriate in the child's culture. Children are internally motivated to conform to these gender schemas, and these schemas often promote stereotypical gender norms.

Sociological Influences

Sociological models propose aspects of the social structure, such as women and men filling different social roles, to explain patterns of behavioral differences between men and women. Social role theory,

social identity theory, and expectation states theory conceptualize social structure as a primary determinant of gender-linked behavior.

Social Role Theory

In most cultures, women have less power and status than men. Women control fewer resources, perform more domestic work, receive lower pay, and are not equally represented in high-level administrative roles. Alice Eagley's social role theory states that gender differences result from these contrasting roles of women and men. According to Eagley, the social hierarchy and division of labor cause gender differences in power, assertiveness, and nurturing behaviors. Because of the status differences in society, women had to adapt to roles with less power and, consequently, developed more cooperative, less dominant profiles than men.

Social Identity Theory

Social identity theory examines how people identify with a social group and how social identity leads to group phenomena such as conformity, cohesiveness, and intergroup discrimination. Social identity theory is based on the three interrelated concepts of social identity, social categorization, and social comparison. *Social identity* is a self-concept developed from belonging to a social group or groups and the value an individual places on a group membership. Once a person internalizes a group identity and incorporates the identity into his or her self-concept, group membership has personal consequences for the individual. *Social categorization* is the cognitive separation of the social environment into social categories. The categorization creates a system of the social world. Individuals can be oriented into society by defining their individual category memberships. The categories of the social world have status and often compete for resources, prestige, and power. Members of powerful groups normally have a positive social identity, and subordinate group members have a more negative social identity. Individuals seek to differentiate their own group positively from others to enhance their own self-esteem. *Social comparison* is the evaluation of groups by comparing them on related dimensions. Depending on one's evaluation of the groups to which one belongs, group membership can have a positive or negative effect on one's social identity.

Social identity theory suggests that gender as a social category will exaggerate male and female differences as individuals seek to differentiate from other groups. Furthermore, when an individual is perceived as a male or a female, the stereotypes of the group, including status, prestige, emotional experiences, goals, norms, and traits, are often accepted by the group members and influence self-perception. With males perceived as the powerful group in most cultures, based on social identity theory, males will have a more positive social identity and self-esteem than females. Also, males and females may accept more stereotypical gender norms and exhibit gender-typed behaviors when defined according to gender group membership.

Expectation States Theory

Expectation states theory focuses on small, task-oriented groups. In these groups, members evaluate their own and each other's potential contributions to the group task to determine how to reach the group's goal most effectively. Because they share cultural beliefs, group members share performance expectations for each other. Expectations for performance are based on status characteristics, attributes culturally associated with different levels of esteem and value. These characteristics can be specific skills relative to the task or diffuse characteristics such as gender, race, education, or age. When a group contains both men and women, participants tend to expect men to contribute more to the group's goal even if gender is not relevant to the task. The expectations become self-fulfilling prophecies. Because of higher expectations of them, men tend to contribute more to group discussion, behave assertively, and emerge as leaders in the group. Even when male and female group performance is identical, men's performance is evaluated more favorably. This theory provides an explanation for how societal beliefs are reproduced in group interactions and helps to explain the influence of beliefs about gender on social life.

Integrative Models

Biological influences provide explanations for gender differences focused on the action of prenatal androgens on the developing brain and differences in activity levels or play styles of boys and girls. Social theories explain the way in which gender roles can be learned either early in life or through societal

pressures. Other researchers suggest biological and social influences interact to produce complex understandings of gender. A biosocial or interactionist model suggests both biological and environmental influences are important and are likely to interact in various ways during development. There are many models of biosocial shaping of gender, and the models are often modified and replaced in light of further findings. The explanations of gender differences are not static and will continue to change as our understanding of human biology, social influences, and societal structures develops.

Promoting Gender Equity in Education

Title IX of the Education Amendments of 1972 was modeled on the Civil Rights Act of 1964 prohibiting discrimination on the basis of race, color, or national origin. Title IX states: "No person in the United States shall, on the basis of sex, be excluded from participation in, or denied the benefits of, or be subjected to discrimination under any educational program or activity receiving federal assistance." The law requires any institution receiving federal funds to maintain policies and practices that do not discriminate based on sex. To help promote gender-equitable schools, the law requires males and females to receive equal treatment. Now, more than 35 years after the passage of Title IX, there are more women in America's colleges and universities, and women receive the majority of master's degrees. Although women have made great strides, some gender differences in America's schools still exist.

Based on achievement test scores, the gap between boys and girls has closed in the United States, and females tend to earn higher grades and are the majority in undergraduate education. Attention is shifting to the underachievement of boys in U.S. schools. Boys are documented as having more discipline problems, lower grades, and higher dropout rates than girls. Boys are overidentified in special education programs and are meeting with less success in the average classroom. Underachievement of boys is an issue; however, there are still issues facing girls. For example, young women lag behind males in mathematics and science achievement in high school and in pursuing degrees in math and science in college. In addition, although women are earning college degrees in record numbers, the average income of a working woman is significantly less than a working man.

Gender equity should benefit boys and girls; it is a complex issue and it cannot be thought of as helping only boys or only girls.

Understanding what gender stereotyping is, why it is so pervasive, and how gender beliefs are developed in individuals, groups, and society can help address gender bias in the classroom. Gender is a salient social category at a young age. Children show extensive knowledge of traditional gender stereotypes as early as the toddler years, and their knowledge increases as they move into preschool. Children link specific toys, objects, activities, occupations, and clothing with males and females based on gender stereotypes, with an exaggeration of between-sex differences and within-sex similarities. Older children make complex inferences using gender-typed characteristics to predict competency, behavior, personality traits, roles, and occupations. Gender stereotypes in children are rigid and highly resistant to change. Studies show children make negative judgments about people who violate gender stereotypes, demonstrating their difficulty in accepting change to their beliefs about gender roles.

For boys and girls to have available a full range of opportunities and choices, students must not be limited by academic, athletic, or career stereotypes. Because children enter school with preexisting beliefs about gender, educators and administrators have the task of providing role models, quality educational materials, and highly qualified teachers who are sensitive to gender-based beliefs and behaviors and who can help children reflect on their gender stereotypes and reshape their beliefs about gender.

GENDER BIAS

Gender bias refers to the differential treatment of individuals based on their gender. Such treatment can be negative or positive and is often subtle and executed unwittingly. Although the phrase frequently describes unfair or unequal treatment of women, it can describe differential treatment of men as well. Gender bias is found in many environments and cultures. Men and women are often assigned different obligations within the family structure and receive unequal treatment in the workplace. Gender bias within educational institutions is of particular importance because of the impact such differential treatment has on child development and later life opportunities. Although great strides have been made to reduce gender bias in the classroom, gender stereotypes are still present. Gender bias in socialization, expectations, teacher interactions, and classroom resources prevent children from obtaining an equal education.

Title IX

Gender bias in education gained attention in the 1960s. Before this, classes were often segregated according to sex, and educational expectations were gender specific. Girls were expected to take home economics, while boys were encouraged to take shop, math, and science courses and participate in sports. In 1972, Congress enacted Title IX, an education amendment that prohibited sex-based discrimination in schools under penalty of loss of federal funds. Since the enactment of Title IX, education in the United States has made significant advancements toward gender equality. However, while blatant forms of gender bias have been removed from the classroom, subtle gender biases continue to exist.

Socialization and Academic Performance

At first glance, it may seem that boys are currently the endangered gender in the U.S. education system. Male students comprise 80% of high school dropouts and 66% of the learning-disabled population within U.S. schools. Compared with female students, male students struggle with reading and writing, receive a higher percentage of failing grades, and are less likely to attend college. However, substantial evidence suggests that despite the fact that females have surpassed males in many ways, girls are still discriminated against within education.
